HYGEIA NURSING BOTTLE

THE CLEANEST, SAFEST, BEST

GLASS FOOD-CELL

TWO SIZES— 8 and 10 oz.

Baby Saver — Lessens Mortality.

THE BOTTLE WITH A BREAST
NO TROUBLE TO WEAN BABY

RUBBER BREASTS —In red or black.

Write for our special offer to physicians.

BUFFALO, N. Y.—1206 MAIN ST.

In Rheumatism and Lumbago

the muscular pain and soreness can be greatly relieved by thoroughly rubbing

K-Y ANALGESIC
"A Power for Comfort"

into the affected area and covering with a piece of soft flannel to keep in the warmth.

Doesn't Blister **Contains No Grease** **Water-Soluble** **Easily Washed Off**

Obtainable of all druggists in collapsible tubes. Samples on request.

Johnson & Johnson
NEW BRUNSWICK, N.J., U.S.A.

Entered as Second-Class Matter, June 24, 1879, at the Post Office at New York, N. Y., under the Act of March 3, 1879.

Supplied in 5-grain capsules, bottles of fifty. DOSE: For adults, one to two capsules three times a day. Children require less in proportion to their age.

Supplied in bottles of 16 ounces. DOSE: For adults, one tablespoonful three times a day after meals; for children, one to three teaspoonfuls three times a day.

Two Effective Vitamine Preparations

METAGEN

All the known vitamines are present in Metagen, and this fact is demonstrated by physiologic tests on animals.

Metagen contains:

Vitamine A (antirachitic)—the fat-soluble vitamine normally present in milk, butter, cod-liver oil and certain plants.

Vitamine B (antineuritic)—a water-soluble vitamine found abundantly in yeast, nuts and the pericarp and germ of grains.

Vitamine C (antiscorbutic)—a water-soluble vitamine of citrus fruits and certain vegetables.

Prescribe Metagen in all cases of vitamine deficiency—rickets, scurvy, malnutrition, marasmus and other disorders of metabolism. It is a valuable adjuvant in the dietetic treatment of tuberculosis, anemia, and the asthenia incident to the convalescence from acute infections.

EMULSION METAGEN AND COD-LIVER OIL

This product exhibits not only the native fat-soluble vitamine of the finest Norwegian oil, but also Metagen—the fat-soluble vitamine from vegetable sources, as well as the water-soluble vitamines.

Considering the pathogenesis of rickets, no available medicament more clearly meets the therapeutic indications than Emulsion Metagen and Cod-Liver Oil—a powerful tonic and metabolic stimulant, containing active concentrates of *all* the vitamines and an augmented supply of the antirachitic vitamine.

The Emulsion naturally suggests itself as a suitable prescription also in cases of malnutrition, scurvy, and other conditions due to vitamine impoverishment.

SOME FACTORS IN BONE REPAIR.*

BY WILLIAM SEAMAN BAINBRIDGE, M.D.,

NEW YORK.

COMMANDER MEDICAL CORPS, UNITED STATES NAVY RESERVE FORCE.

WHEN confronted with a fracture of one of the long bones, the surgeon, like the anxious miner straining his vision for the first glitter of gold in the ground, is inclined often to focus his entire attention upon the local lesion with a zeal which would be highly commendable were it not for the fact that this fixation of his mind upon a single point is apt to result in the disregard of conditions operative at a distance from the broken bone, but nevertheless of important bearing upon its repair. His curative endeavors are centered at once upon the mechanical adjustment of the fragments, and his aim is their direct longitudinal apposition, without lateral deviation, after conscientious removal of any infection from without and equally careful exclusion of all foreign material—which here means also muscular or other tissue intervening between the separated bone-ends. The fracture having been "set" to his satisfaction, the expert surgeon proceeds to utilize the best appliances at his command for holding the fragments in place without undue pressure or laxity, so that the circulation may not be impeded by an overtight appliance, nor harmful excursion of the bone permitted by a loosely fitting one.

Among mechanical appliances used in the management of fractures of the long bones the Thomas splint is generally credited with being a most useful and practical splint for the thigh and leg. The half-ring modification or the Hodgen wire cradle extension suspension splint are accorded the preference in certain cases. In the experience of many war surgeons the Lane metal bone-plate was found to be excellently adapted to the reduction and immobilization of various types of fracture. The soft crucible and tool steel used in the manufacture of the Lane bone-plates and screws is advantageously replaced in Sherman's modification by stronger plates and screws constructed of elastic vanadium steel. Some valuable by-products of the unprecedented clinical experience of the World War, applicable also to the requirements of civil practice, are represented by Willems' screw extension for fractures of the thigh and leg bones; Blake's extension apparatus for the treatment of complicated femoral fractures; Sinclair's stirrup and splints; the practical ice-tongs calipers devised by Besley and modified by Pearson; the narrow, flexible cast-iron bands of Sir Robert Jones; Magnuson's absorbable ivory plates and screws; the animal bone-plates and screws recommended by Brougham and Ecke; Brenizer's intramedullary and extracortical beef bone splints for the repair of fractures of the long bones; Henderson's beef bone screws for fractures and bone transplantation. The admirable output of human ingenuity and professional skill embodied in these and other modern methods of fracture treatment has undoubtedly resulted in the saving of many limbs without discrediting some of the older tried and tested appliances, such as Lambotte's extensible steel fixateur or skewer and Reelus' walking stirrup for the treatment of delayed consolidation of leg fractures. During the reconstruction work at U. S. General Hospital No. 29, Fort Snelling, Minnesota, some new improved splints and appliances have very recently been developed, including an attachment for the Thomas leg splint which may be used with either a full-length or shortened splint, and on each side. The method of fastening the attachment to the Thomas splint permits of adjustment to fit the length of any thigh. The advantages of this method are that by its use fractures of the femur can be treated with the knee flexed and active or passive motion at the knee may be employed.

In the treatment of fractures which refuse to unite bone-grafting is often successfully resorted to, especially in the form of Albee's inlay cortical graft. Intramedullary pegs have given satisfaction in fractures of the radius or ulna, whereas long, stout inlay grafts give the best results in the case of the humerus and femur. The fact that in old ununited fractures the bone near the site of fracture is sclerosed and avascular, interfering with the establishment of a sufficient blood supply, is unfavorable to the outcome of a grafting operation and at the same time renders the employment of very prolonged fixation inadvisable.

All these modern methods of fracture treatment, the outgrowth of incomparable experience in handling large series of cases in military practice, are important, and some have a wide sphere of usefulness, but it must be kept in mind that the union of fractures also depends upon a number of factors entirely outside the adjustment of the loose bone-ends and their maintenance in place. Without exception, the fixation methods, including

*Read at the Congrès International de Médecine et de Pharmacie Militaires, Brussels, Belgium, July, 1921.

those which permit a certain amount of motion between the fragments and thus provide for better nutrition, unfortunately expose to the danger of delayed union, sometimes with bending and buckling of bone and extensive callus formation. There is no method of fixation at our disposal which directly favors or hastens bone union and repair of fractures. This is a very important truth, especially in view of the advanced status of orthopedic technique which is hardly capable of further improvement, for we are thus obliged to look for improved results of fracture treatment in an entirely new direction. As admirably stated by Sir Anthony Bowlby, all young surgeons must be trained to realize that the so-called "setting" of the fracture should be really only the beginning and not the end of surgical treatment.

There are some factors which undoubtedly militate against a favorable course of bone repair, but which from a strictly therapeutic viewpoint have been almost disregarded in this connection. When called upon to initiate or supervise a process of repair in a fractured bone, the surgeon should keep in mind certain conditions under which bony growth is more or less interfered with. In the first place, *endogenous infectious processes* in the bone-marrow may lead to local congestion and disintegration. In the explanation of rickets some investigators have assumed the action of known and unknown infectious substances which are carried especially to the points of physiological hyperemia of growing bones at the ossification centers. Epidemics of rachitis and osteomalacia, caused by a diplostreptococcus, were observed by Morpurgo (1907) in rats, and inoculation of this coccus reproduced the same bone symptoms in other animals. It has also been shown that after infectious diseases, such as measles, scarlet fever, and diphtheria, bacteria are deposited by the bloodstream in the vicinity of the epiphysis, where they may give rise to changes corresponding both macroscopically and microscopically to those seen in rickets. It is a rational conclusion that injurious factors of this kind which exert a weakening influence upon unbroken bones will retard or prevent the repair and consolidation of fractures. Curvature of the femur is known to occur occasionally in connection with suppurative processes of the knee joint, and is presumably due in part to bone-infection by a contaminated blood supply, besides the weight brought to bear upon the femur when the patient attempts to walk, to which it is commonly attributed.

The fact must not be overlooked that lesions of infectious origin, from both without and within, are of frequent occurrence in bone. External infections may extend inward through the cortex of the bone, an internal infection traveling by the opposite route. The tendency of bone-infection is to extend widely beneath the periosteum, or through the marrow spaces, causing more or less extensive necrosis of the bone. Aside from the *Staphylococcus aureus*, which is the most common pathogenic agent in bone-infection of endogenous origin, other germs may be responsible, such as the *Streptococcus pyogenes*, the pneumococcus, the gonococcus, or the typhoid bacillus. In certain cases of acute inflammatory atrophy of bone following upon secondary infection of adjacent joints the presence of the gonococcus has been demonstrated. It might be worth while to investigate the relative frequency of gonorrhea in fracture cases where healing is delayed. "La goutte militaire" must be regarded at least as a suspect in those cases in which no other explanation of the deficient callus formation and bone repair is forthcoming. In view of the long persistence of the typhoid bacillus in the body, as shown by the frequency of healthy "carriers" who have recovered from the disease but still harbor the parasite, it is perhaps not an exaggerated precaution to ascertain the existence of a positive or negative typhoid history in all cases of delayed union, if not in all fractures of the long bones.

As regards *focal infection* and its rôle as a factor in the repair of bone, it is suggestive that according to recent investigations of Pemberton (1920), on the nature of arthritis and rheumatoid conditions, the army furnished 400 cases of chronic arthritis, 298 of which showed demonstrable surgical foci, mostly in the tonsils (208), the remainder in the teeth or in the genito-urinary tract. Removal of the infectious focus and correction of the altered metabolism by regulation of the diet were found to have a beneficial effect on these disturbances.

Constitutional diseases, such as tuberculosis and syphilis, are undoubtedly responsible for delayed union in a certain number of cases. It is noteworthy in this connection that syphilis, according to recent investigations, appears to have such a pronounced structural effect upon the metabolism of bone tissue as to leave more convincing proof of an old luetic infection on the *x*-ray plate than is afforded by the Wassermann or Noguchi tests.

Other latent infections or uncorrected irregularities which have not yet been challenged as factors capable of affecting the growth and solidification of the callus are evidently responsible in a number of obscure cases of ununited fracture. A very instructive case which illustrates the leading part played by remote conditions in certain cases of delayed union, came under my personal observation in the United States Naval Hospital, New York, N. Y. Amputation to the thigh had been performed on one side, and the other femur presented a fracture, the fragments overriding four inches, a condition which had persisted until the tendons were shortened and the bone-ends could be placed in a position only by forcible extension. Two Lane plates were adjusted and held the femur in mechanical apposition, performing a useful function by lengthening the contracted muscles, but at the end of some months no callus had formed, while the flesh wound had healed and the general condition was fair. There evidently was a flaw in the metal of one of the bone plates, for it broke—an accident otherwise difficult of explanation—under careful employment of physiotherapeutic measures or perhaps lifting the patient cautiously from chair to bed. It was hoped for a time that the resulting irritation through the broken plate, with the associated mobility of the thigh, would

stimulate the production of callus, but the fracture refused to unite. After the plate had been removed, it was possible to insert a bone-graft from the tibia and to hold the fragments in place without undue pressure by retaining apparatus. Still, practically no callus developed, although the soft parts healed readily, and the fragments were in perfect apposition. About this time the aggravation of certain symptoms which had existed for several months began to divert our attention which had naturally centered in the intractable fracture, to the patient's general and particularly abdominal condition. Periodical attacks of vomiting, after nearly every meal, had been noted for nearly three months, and the clinical evidence in the form of general abdominal discomfort, obstinate constipation, and typical attacks of pseudocholecystitis strongly pointed to intestinal stasis. Abdominal section was performed, showing well-marked bands and adhesions, which were corrected, to the great relief of the patient, who after the abdomen had been put in proper shape vomited only three times as a direct result of the anesthetic, after which all vomiting was definitely at an end. But the most interesting result of the abdominal intervention, from the viewpoint of the present consideration, is the postoperative production of a strong progressively solidifying callus in the fractured femur. The lesson taught by this experience is so convincing that all comments would seem to be superfluous, and I will only repeat that the healing of a broken bone imposes a tax upon the resources of the general organism for which the body must be fitted by removing or correcting irregularities of all kinds which may and do interfere with the normal course of bone-repair.

The gastrointestinal tract, with its many side pouches, recesses, cul-de-sacs, and extensions, such as the gallbladder and appendix, for example, naturally represents an important centre of dangerous foci of infection. The existence of local disease will inevitably delay the repair of fractures, not only on account of the ever present risk of metastatic localization of microbes or toxins at a point of lowered resistance, such as is offered by a fracture, but because of the associated lowering of the immunity balance due to the existence of infection and the more or less successful establishment of tolerance on the part of the organism. Being already taxed and perhaps exhausted by the fight against one enemy, the defensive mechanisms are sometimes unable to achieve a victory at the other front.

It is gradually being realized that in disablements of the human machine from any cause the patient must be treated as a whole, instead of being considered for the time being as an inevitable but superfluous appendage to his goitre, malignant tumor or other diseased condition. This truth has long been appreciated by advanced clinicians, who would not dream of treating goiter, gallbladder, or gastric disease, for example, without giving the closest attention to the manner in which other presumably intact organs discharge their obligations. Among operating surgeons, however, there is perhaps still a tendency to concentrate all efforts on the part that is in immediate need of repair, and a corresponding inclination to wonder that an apparently highly successful operation sometimes fails to accomplish the confidently anticipated result. A broken skull or thigh often absorbs all the attention of the surgeon, who lavishes his best skill and technical ingenuity on the repair of the existing lesion. But the ideal treatment of fractures must take in more than the broken bone and the resulting displacement.

So much excellent work was done in the direct treatment of fractures of the long bones in particular, in the unprecedented clinics provided by the World War, that there is practically nothing left for me to add to this important phase of the subject. On the other hand, the reasons for delayed or missed union and for remote imperfect results in spite of the most up-to-date operative procedures, still remain to be collected, compared, and explained, so that it may not be unprofitable to pass in review some of the obstacles to bone-repair and restoration of function, with suggestions as to their origin and possible control.

The greatest stumbling block in the way of tissue-repair is well known to consist of infection, and the lessons taught by the World War are still fresh in all our minds. The mere word suggests contamination of soil, purification of wounds, débridement, primary excision, and suture. But one of the points I wish to emphasize is that infection does not necessarily come from the outside. As a matter of fact, many injurious microorganisms lurk within the human system, where under ordinary conditions they may do no apparent harm, but as a result of autoinfection due to exacerbation of a latent or quiescent microbism are in all probability capable of retarding or preventing the recuperative and reparative processes of the body. Recent war experience has drawn attention to this possibility which occasionally was found to account for the peculiar and otherwise inexplicable behavior of apparently sterile wounds. The explanation is probably to be sought in the disturbance of the immunity balance—which every human body in the course of its existence has established for itself—by the abrupt onset of a more or less complete and persistent loss of local resistance at some point of the intricate human machinery. However, the condition still remains relatively unknown, although as regards their number and range, the disturbances produced by these internal foes are probably not inferior to diseases caused by microbes introduced from the external world.

Medical antisepsis must be constantly on the alert, not only against the enemies at the gate, namely, at the site of the fracture, but also against those which do their nefarious work hidden behind the bulwarks of the body. Some of their most important and dangerous strongholds are represented by the mouth cavity, the tonsils, and the nasal accessory sinuses. All these structures not only harbor highly pathogenic germs but furnish a favorable center for their distribution in the body at large. A certain degree of tolerance becomes gradually established through the constant presence of these agents, but the defense is apt to break down as soon as the inflic-

tion of an injury lowers the normal resistance of a given portion of the body.

With special reference to the relation between lowered resistance on the part of bones or joints and hematogenous infection, one of the earliest experiments along these lines (Schüller, 1880) showed that the introduction of tuberculous material by way of the lungs, followed on the same day by artificial contusion of the knee-joint or infliction of fractures, in rabbits and dogs was regularly followed within two to four weeks by a progressive inflammation of the traumatized joint, with externally demonstrable articular swelling, found to be of tuberculous origin at the autopsy some weeks or months later. The damaged bones were sometimes found to contain sharply outlined collections of tubercle bacilli. This experiment affords a good illustration of the rôle played by traumatism and lowered resistance in the localization of infectious material contained elsewhere in the body. Another suggestive case in the older literature (König, 1884) concerned a young man who had a kyphosis, with symptoms of incipient pulmonary tuberculosis, but was in fairly good condition when he sustained a fracture of the ankle. In spite of suitable treatment, the foot remained swollen and abscess-formation with fistula supervened. Unmistakable tuberculosis of the ankle joint developed and about six months later the patient died. At the autopsy a small tuberculous bone-focus was found at the site of the fracture, with advanced synovial tuberculosis in the joint. This case was undoubtedly one of metastatic tuberculosis lodging in a non-resistent fractured bone. Osteomyelitis experimentation points in the same direction. Kocher showed that after intravenous injection of the pathogenic cocci osteomyelitis developed only in those bone-areas which had previously been damaged by traumatism. Of recent years Murphy of Chicago and others have repeatedly emphasized the buccodental or tonsillar etiology of joint suppurations and related disturbances. The accessory nasal sinuses are responsible in a certain number of the cases. If under ordinary conditions of weak health a normal joint is unable to resist the invasion of buccopharyngeal microbes, but reacts in the form of pain and disablement, it is not surprising that in the presence of a local focus of infection the repair-process of a broken bone should be delayed or very imperfectly accomplished. Even in the absence of demonstrable disease of the teeth or tonsils, the knitting of the fractured bone may be prevented by the injurious influence of pathogenic germs in an apparently healthy buccopharyngeal cavity. Such microbes have long been known to reach the lungs, the ears, the cerebral meninges, and other structures where they may give rise to serious and sometimes fatal disturbances.

One of the reasons why harmful germs may lodge a long time in the mouth without causing trouble is to be sought in the physical integrity of the buccopharyngeal mucosa. But the normal standard of the mucous membranes of civilized man is easily disturbed by local traumatism, the devitalizing effects of cold, the inevitable neglect of the hygiene of the mouth in particular under the exigencies and privations of warfare. At the time of my visit to the hospital of the Indian Medical Service Corps in Boulogne, in 1915, I learned that the natives at home are in the habit of cleaning their excellent teeth with small sticks of a special wood. In the hospital no less than 60 per cent. of the men had pyorrhea alveolaris, undoubtedly due to neglected teeth, for tooth-brushes were not accepted—as being made of pig's bristles, in other words, unclean according to their religious teachings—and difficulty was naturally encountered in supplying the special sticks to which the Indian soldiers were accustomed. This apparently trifling observation is extremely suggestive, and, in fact, contains the key to some obscure problems of wound-repair in general and bone-repair in particular. Local susceptibility to microbic invasion must be supplemented by acceptance, or what Netter of Paris calls the consent, on the part of the body as a whole, in order to result in secondary infections and systemic disturbances. Here again, those conditions are admirably complied with by the lowering of the general resistance incident to the restrictions of hospital life. Fortunately, the degree of virulence of buccopharyngeal microbes is subject to fluctuations, the reasons for which are not yet entirely understood, and their capacity of interfering with the processes of tissue-repair varies in proportion.

When confronted with the task of restoring the integrity of a fractured bone, the surgeon therefore must learn to look at the patient as a whole and to put him in the best possible general condition. A man used to an active, out-of-doors existence, with constant contraction and relaxation of muscle and the active oxydation-processes belonging to the same, suddenly finds himself stretched out in bed, or at best confined to the ward, with more or less loss of physical and mental tonus; all the cells of his body share in the suspension of work, with the result that resistance is lowered and defenses are gradually sapped. Meanwhile, a polluted blood supply contaminates the seat of the fracture, and as the circulation is sluggish tarries in the surroundings of the broken bone-ends, undermining their reconstructive energies.

The callus for the repair of the fractured bone is expected in a measure to form from the hematoma. Fractures do not consist merely of a broken and more or less displaced bone, but as we know, all bony injuries are associated with a bloody extravasate, which in closed fractures may remain subperiosteal or pass into the surrounding tissue, or in open fractures escape to the outside. The loss of the extravasated blood has an undesirable influence upon the repair process in so far as its presence undoubtedly favors the formation of the callus. On the other hand, aside from the danger of infection from without or within, the hematoma may exert an injurious pressure upon the neighboring organs, causing congestion and lymphstasis, which are further increased by muscular inactivity. This retardation of the blood- and lymph-current involves a more or less imperfect nutrition of the surrounding tissues and at the same time exposes them to the danger of *auto-*

infection. The causative relation between the hematoma and the appearance of the callus is shown by certain cases of clean open fractures in which the blood has escaped to the outside, with the result that a very weak callus is formed. On the other hand, it is a familiar fact that a sluggish callus-formation can be hastened through the injection of blood at the site of the fracture or through artificial production of a hematoma by rubbing the bone ends against each other.

The young callus at first has the character of granulation-tissue, but later on gradually increases in solidity through deposit of lime salts. Its *mechanical* properties are of great importance from the therapeutic viewpoint. Newly developed callus is semi-elastic and yielding, so that it becomes readily deformed under the influence of relatively slight forces, resuming its original shape after these forces have ceased to act. But the semi-elastic callus is unable to overcome a marked deformity, which is apt to become permanent, the callus weakening and giving way under its influence. The frequent repetition of injurious factors, including irritation by endogenous pathogenic microbes and their toxins acting upon the young callus frequently results in a pseudo-arthrosis, which means that no bony but merely a fibrous union has occurred. Provided all mechanical rules have been observed, pseudo-arthrosis is probably referable to latent microbism in the majority of the cases. The solidity of the *exuberant* callus, which is sometimes formed as a result of latent infection, is due to its great bulk which counteracts its softness. When this mass later on undergoes a transformation into bone-substance, it acquires a much greater solidity than necessary. Before these superfluous bony masses can be reabsorbed through the osteoclasts they may exert an injurious action through pressure upon adjacent structures, impairment of articular movements, or formation of ankylosis. In other cases the abnormal callus interferes with adjacent organs, especially nerves, resulting in atrophic changes. Exuberant callus will also develop when the two bone-ends are more or less displaced or imperfectly adjusted. After consolidation has taken place in these cases the large callus serves to strengthen the bone, which always needs added support when its longitudinal axis is displaced.

The softness of the young callus requires fixation of the injured limb, at least to the degree that the slight restricted excursion does not exceed the elasticity of the callus. The *rest,* however, which is needed for the reunion of the broken bone retards the blood and lymph flow, while condemning the muscles to inactivity and exposing them to the danger of atrophy of disuse. As soon as possible during fixation, functional treatment (introduced by Lucas-Championnière) should be instituted in the form of exercises of the muscles, tendons, and joints, so that their recovery may proceed along with the repair of the fractured bone. A very common cause of badly healed fractures of the long bones consists in stiffening of the adjacent joints, usually associated with incomplete correction of the displacement of the broken bone-ends.

It is not my intention to enter into a critical discussion of the various methods of treating fractures, but rather to emphasize also in this connection that the broken bone must not be considered exclusively, nor even receive the lion's share of professional attention. The muscles and joints must be given the benefit of early massage and judicious exercises, chiefly in the form of active movements in small excursions. A fracture is not to be considered as healed when the bone has anatomically united, but the muscles are damaged or the joints are stiff. The bad effects of immobilization in this respect led Dowden to the elaboration of the no-splint treatment of fractures. In cases of fracture of the humerus, for example, active movements of the fingers and wrist are encouraged from the first, together with pronation and supination, and the patient is instructed to flex and extend the elbow to a limited degree; three or four days later, passive movements are begun, aiming at complete extension of the elbow. It is certainly suggestive that in ten years he had no case of non-union or other untoward sequelae. Ideal results can be obtained only by attending at the same time to all requirements, from correct position of the fragments and creation of the best possible physiological conditions for the muscles and joints, to the patient's general health and the removal of all foci of latent infections. The existence of an infectious focus at any point of the body often constitutes a serious obstacle to the healing of all fractures.

The mobilization of quiescent microrganisms through changed circulatory conditions is very clearly brought out in a case of tetanus infection, observed in Germany during the war, as a sequel of artificial stimulation of the callus, for ununited gunshot fracture of the humerus, the injury dating back three and a half months. The flesh wound had healed and there was no other demonstrable lesion of the body. Four days after the loose fragments had been rubbed together the patient was attacked by tetanic spasms, suggesting that tetanus spores had penetrated into the arm with the artillery projectile and remained viable for a long time between the bone-ends, until their development was favored by the surgical traumatism. The most interesting feature of this case from our viewpoint is that this fracture had failed to consolidate, presumably as the result of the latent bone-infection.

The fact is not always appreciated that the complete repair of the broken bone does not necessarily coincide with a complete functional cure, but really does so only under the most favorable conditions, whereas months or even years may intervene in other cases. The less the soft parts have been damaged, the more they have been exercised during the repair of the bone, the more likely are they to recover together with the bone. On the other hand, when the soft parts, especially the muscles, tendons, and tendon-sheaths, have been badly damaged, perhaps with involvement of adjacent joints, a functional cure is naturally delayed and may remain incomplete for a long time. In the great majority of cases, under adequate treatment, no further improvement of function is to be expected at the end of two or three years. Certain sequelæ, more particularly chronic arthri-

tis, may persist a long time, especially in those cases where latent microbism has found a favorable soil for colonies in the traumatized and nonresistant tissues.

There is reason to believe, moreover, that aside from autoinfection with buccopharyngeal microbes, a deficient or faulty *action* of *internally secreting glands* may be in part responsible for delayed union or non-union in fractures of the long bones. The endocrine glands undoubtedly exert some influence upon the bone-system, under physiological as well as pathological conditions. The growth of bone is known to be injuriously affected by the diminished or exaggerated function of certain ductless glands, notably the thymus, the thyroid, the parathyroids, and the suprarenals. The relation of the internal secretion of the ovaries to the health and strength of bone is well known, but may be left out of consideration in a review of endocrinic factors governing bone-repair in military fractures; nor is there reason to dwell upon the action of testicular hormones in these cases.

The existence of close relations between the *thymus* gland and the ossification-process has been repeatedly emphasized in the international medical literature. By Frontali in Italy (1920) the thymus gland of a child thirty-three days old with congenital fragility of the bones and entire absence of the compact substances from the shaft bones, but with normal calcium balance and lime-contents of the blood, was found to be in a state of advanced sclerosis and atrophy. The other internally secreting glands were normal, so that he is inclined to attribute the deficient bone-development to the changes of the thymus and to recommend therapeutic injections with the serum of a child having a normal thymus gland, in cases where the function of this organ is deficient. Extirpation of the thymus in growing animals is usually followed by disturbances of ossification resembling rickets and leading to spontaneous fractures. The behavior of young dogs with artificial fractures of the long bones was found to differ greatly, after the performance of thymectomy, from the behavior of control animals of the same age and size whose thymus gland had not been extirpated. Whereas in the latter a strong callus rich in calcium made its appearance, the thymectomized animals developed only a very scanty and imperfect callus. Sometimes there was no demonstrable attempt at callus-formation at all, and a connective-tissue pseudoarthrosis developed instead. The effect of thymus-feeding upon artificially produced fractures in animals was recently (1918) investigated by Glaesner, with the object of ascertaining, in the interest of human surgery, if a more rapid repair of bone defects can be secured by the administration of thymus substance. Rabbits of the same litter served for these experiments in which a circular defect of the tibia was produced by means of a trephine; some of the operated animals were then regularly fed with thymus gland substance, others which received no thymus serving for controls; all were kept on exactly the same diet. The size of the bone-wound was ascertained once a week by *x*-ray pictures. After a certain time (four weeks) the animals were killed and the tibias of the treated and normal rabbits were examined and compared, with the result that very striking differences in favor of the former were noted. These findings undoubtedly suggest a beneficial influence of thymus administration upon the repair of bony lesions, and it seems not improbable that these experiments may acquire practical importance for the prevention of delayed union in fractures of human shaft bones.

The marked nutritional disturbance set up in the organism as a result of *thyroid insufficiency*, partly in the form of incomplete decomposition of the albumins, partly in the form of deficient oxydation of the fats, was discussed several years ago by Hertoghe of Antwerp, and he emphasized the fact that all tissues of the body are affected by nutrition or malnutrition, respectively. In the presence of thyroid insufficiency, no tissue remains unchanged, and the bones are no exception to the general rule. The administration of thyroid products is followed by extremely favorable results in cases of this description. The favorable effect of thyroid preparations upon the repair process after fractures is known to be due to the resulting acceleration of the deposit of lime-salts. A French observer, Gauthier, a number of years ago published observations on cases of delayed union and pseudarthrosis, cured by a fortnight's administration of altogether six to ten grammes of fresh sheep's thyroid, and these findings were confirmed by several other investigators. In 32 of 37 cases of delayed union, the fracture became promptly consolidated, in Gauthier's experience, evidently due to the stimulating effect of the thyroid extract upon the osteogenetic tissue. During the repair process, a large callus developed, which underwent retrogressive changes when the thyroid medication was stopped. Fractures of the long bones are said to have healed within three weeks (seventeen or eighteen days). Gauthier accordingly recommended the routine administration of thyroid extract, from the start, in the treatment of fractures. Animal experimentation has shown that removal of the thyroid gland, after a fracture has been inflicted, leads to delayed consolidation of the bone in practically all cases without exception.

The *parathyroids* in their turn are also known to exert a regulating influence upon the calcium metabolism. By some observers, the tetany which follows upon the extirpation of these small bodies has been referred to a deficiency in calcium in the organism as a whole. Leaving aside the tenability of this theory, the fact that interests us here is the potential part played by functional disturbances of the parathyroids, as a result of undernutrition or other causes, in the complicated process of bone repair.

The action exerted by the *suprarenals* on bone repair probably constitutes a highly intricate process. Stress and strain, physical as well as mental, which after all are the conditions under which most fractures are inflicted, through their effect upon the nervous mechanism of these glands presumably diminish the output of sugar into the blood and thereby reduce its bactericidal powers. The impairment of the glycogenic function and the chemical alteration of the blood inviting intravascular and intracellular infection, the invading bacteria are no

longer prevented from penetrating into the depth of the traumatized tissues, and the metabolic dyscrasia ultimately results in delayed bone repair.

The direct beneficial influence of *adrenalin* upon bone repair and callus formation was pointed out several years ago by Carnot and Slavu, who in their animal experiments observed a better bony consolidation in dogs which were given a daily subcutaneous injection of 6 milligrammes of adrenalin, as compared to control animals of the same age and weight whose tibial fractures were allowed to heal without adjuvant adrenalin medication. Even to the unaided eye, the favorable influence of adrenalin upon the process of bone repair was clearly apparent, and these findings were confirmed by microscopical examination. There seems to be a reaction on the part of the bone marrow on the one hand, while on the other there is an increased deposit of lime salts under the influence of the drug.

The *cerebral hypophysis* or pituitary gland is known to affect the osseous system, a disordered function of this organ leading to the changes of giantism, dwarfism, and acromegaly. Opinions are still at variance, however, as to the manner in which this influence is exerted. Experimental injection of pituitary extracts in particular has yielded variable results in the experience of different investigators, in the form of delayed or hastened bony growth, increased or diminished excretion of calcium. Just before the outbreak of the World War, in 1914, Marsiglia in Italy published investigations concerning the effect of the active constituents of this organ upon the healing of fractures and the formation of the callus. The outcome of his experimental intramuscular injections of a preparation of fresh whole calves' hypophysis into dogs, whose femurs had been fractured on the day of the injection, was not only negative as regards the acceleration of the repair process by pituitary medication, but he was actually enabled to ascertain a delayed callus formation as compared to the control animals.

In this connection, mention may be made of *gelatine*, a product derived from bony, cartilaginous, and connective tissues, which was originally and very successfully employed to promote the consolidation of fractures, by Anzilotti of Pisa. A sterilized solution of gelatine (2.5 per cent.) is used together with sodium chloride (0.75 per cent.), phenol (0.50 per cent.) and calcium chloride (0.50 to 1 gramme per cent.). A dose of ten c.c. of this solution is injected daily or every other day into the muscles or under the skin. The results, in the form of improved healing of fractures, are claimed to have been uniformly excellent, without untoward sequelæ of any kind.

Upon the basis of these experiences, as briefly sketched in the foregoing remarks, the question naturally arises if the administration of carefully selected endocrinic extracts, known to exert a stimulating effect upon bone growth and ossification, might not be advantageously introduced as a routine feature into the treatment of fractures of the long bones. In all probability, the normal function and cooperation of several internally secreting glands is essential to the utilization of the calcium and phosphorus contained in the food, in the metabolism of the bones. At the present limited stage of our knowledge, the subject may be tentatively envisaged from two viewpoints, referring the disturbances in the repair process either to general malnutrition, with involvement of the endocrinic glands; or possibly to the absence of the indispensable vitamines, damaging the function of these ductless organs.

Vitamines are nitrogenous crystalline bodies of very complicated structure, existing in fresh animal and vegetable foods. Aside from general nutritional disturbances due to the absence of vitamines from the diet, peculiar systemic disturbances of the bony framework of the body have recently been described in Germany and in Austria, where they assumed an endemic character. Much attention has of late been devoted to diseases due to restriction of fresh animal and vegetable foods, with absence of vitamines from the diet, and these conditions are sometimes grouped together under the heading of "avitaminoses," comprising scurvy, beriberi, pellagra, infantile scurvy, rickets and osteomalacia. The vitamines, aside from their absence in unsuitable foods, may be destroyed by mechanical or chemical processes or through the action of excessive heat. In experiments upon young guinea pigs and other animals, not only scurvy-like conditions but actual changes of the bones have been produced through exclusive feeding with highly sterilized cows' milk. Dietetic errors in the form of a deficiency of calcium in the food are naturally capable of inducing an impoverishment of the bone in lime. Disturbances in the phosphorus metabolism also enter into consideration, for it has been shown experimentally that the bones may become decalcified through continued administration of food poor in phosphorus, leading to osteoporotic changes, proliferative processes in the periosteum and cartilages, thickening of the epiphysis, and curvatures of the bones.

Empirical proof of the favorable influence of fat-soluble vitamines on the growing and mature osseous system has long been furnished, through the beneficial effect of codliver oil on rachitic children, this substance being extremely rich in these vital supplementary food constituents. Comb honey also has been shown to contain a moderate amount of fat-soluble vitamine, but this is entirely lost in the commercial strained product. Denatured and so-called predigested foods, if not positively injurious, undoubtedly deprive the body of important building material and are probably in part responsible for incomplete reconstructive processes of various kinds. The harmful action of defective foods on the teeth, and their part in the production of caries, has often been discussed in the dental and orthodontic literature. Through an unsuitable diet consisting entirely of soft starchy foods, disturbances in the form of osteoporosis have been experimentally produced in the growing bones of young dogs; the absorption of the bone substance was increased and the formation of new bone was diminished, as compared to the controls.

The same factors which are concerned in the non-traumatic diseases of the bones and joints are likewise operative in bone repair after fractures. Blood chemistry no less than blood bacteriology enters into consideration in the complicated repair process of fractured bones, and the significance of chemical factors must not be lost sight of in this connection,

for the normal course of bone repair is often arrested by chemical change without bacterial invasion. All fractures are accompanied by a lowered local vitality, due in part to a changed blood supply and diminished nutrition. Absence of the normal bone salts is demonstrable in many cases, and this departure from the normal standard is visible to the experienced eye in *x*-ray plates of the affected bones. My own experience includes cases in which no callus had formed although the mechanotherapy could not be improved upon. Without any other modification of the treatment, these patients were given calcium salts for a variable length of time, according to requirements, with the result that callus formation and union were promptly obtained. One such case is at present under my care in the Naval Hospital and the healing of the fracture is making satisfactory progress.

The value of calcium triple phosphate as a stimulus to osteogenesis has been pointed out by Albee and Morrison, in whose experience the injection of 1 c.c. of a five per cent. solution into the bone defect of rats, on the third day after the infliction of a fracture, was followed as soon as five days later by the beginning of callus formation, shown by *x*-ray pictures, with union of the bone ends at the end of two weeks, whereas in the controls the defect was not yet bridged over after thirty days and only a slight callus formation was demonstrable.

Although ten years have passed since the bearing of focal infections on bones and joints was first pointed out, by Hunter in London, this subject is only gradually receiving the wider attention of the medical profession. Judging from reports in the literature, opinions are still about equally divided as regards the etiological rôle of mouth infections in bone and joint metastasis, for example. However, the existence of latent microbism and autoinfection is generally conceded, and the fact is freely admitted that disease is not exclusively due to agents introduced from without. What remains to be enforced is the application of this principle to the course of repair processes in the body in general and in fractures of the long bones in particular. The defensive mechanisms of the body must be constantly on the alert in the prevention of exogenic as well as endogenic infections. Sir Almroth Wright, in 1919, in his memorable Address before the Royal Society of Medicine, entitled, "Some New Prospects in the Field of Therapeutic Immunization," offered a new explanation applicable to the lodging of bacterial emboli in bones and joints. "A region of the body in which the guardian elements of the blood have been rendered impotent, or as the case may be, have been excluded," is designated by him as an ecphylactic region, and such a region may be induced by *any influence which interrupts* or closes down the *arterial supply* to the part. A fracture would seem to provide an ecphylactic region par excellence.

The modifications of the regional blood supply incident to a break in the continuity of a given bone naturally play an important part in the repair of the lesion. Injury of the nutrient artery of the broken bone is often an inevitable concomitant of all fractures. A number of delicate new blood vessels are formed in Nature's effort at compensation, for the maintenance of a sufficient blood supply. When the extension of the contracted parts is not very carefully timed and manipulated, the stretching of all the regional blood vessels results necessarily in diminution of their caliber and nutritional impairment of the area supplied by them. A highly injurious influence may thus be exerted upon the constructive metabolism of the bone. In order to obtain the best results in the treatment of fractures, practical application must be made of the war taught lesson that the *normal* circulation, nutrition, and mobility of the injured limb must be maintained as far as possible, thereby insuring the vitality of the parts and favoring the formation and solidification of the callus, while guarding against the wasting of muscles and the stiffening of joints.

The many concealed factors at work in the complex process of bone repair which are entitled to serious study in behalf of improved results of fracture treatment are only beginning to be understood and appreciated, so that a promising field is thrown open for further investigation along these lines. The factors influencing bone repair after fractures may be briefly summarized as follows:

I. Blood bacteriology:
   (*a*) Lowered resistance of fractured bone, favoring autoinfection and deposit of infectious agents from the blood (latent microbism).
   (*b*) Metastatic infection of fractured bone, from concealed foci in the tonsils, teeth, gastrointestinal or genitourinary tract.
   (*c*) Constitutional disease, such as syphilis affecting the structural metabolism of bone tissue.

II. Blood chemistry:
   (*a*) Action of internally secreting glands.
   (*b*) Metabolic dyscrasias.
   (*c*) Effect of vitamines, changes in phosphorus and calcium metabolism.

III. Interference with the constructive metabolism of bone through injury to the nutrient artery and changes in the caliber of the regional blood vessels.

Diseases are often called functional, merely because no organic basis for the existing disturbance can be demonstrated, but this apparent absence of course does not exclude the possibility of an organic lesion as the source of the symptoms. Modern experience teaches that toxic infectious processes are to be reckoned with in numerous obscure conditions, and delayed bony union after fractures, for which no satisfactory explanation can be found, undoubtedly is one of these conditions. It may be that the injured bone is affected by minute vascular changes, as the invisible anatomical expression of an endogenous infection or intoxication. The solving of these questions must be left to future investigations by laboratory methods and animal experiments. But the time has arrived for all surgeons to realize the fundamental therapeutic importance of the problem of a possible endogenic cause or metabolic dyscrasia for delayed union after fractures. Convinced as I am of the necessity for more accurate study along these lines, I have endeavored to point out these new vistas in fracture treatment, by inviting attention to some factors in bone repair.

34 Gramercy Park.

TREATMENT OF RAYNAUD'S DISEASE WITH THYROID EXTRACT.

By EDWIN W. HIRSCH, M.D.,

CHICAGO, ILL.

August Maurice Raynaud was born July 5, 1834, in the city of Paris, and achieved distinction and position principally by his thesis for the medical degree, which was entitled "De l'Asphyxe Locale, et de la Gangrène Symmétrique des Extrémités." Raynaud received the degree of Doctor of Medicine and Doctor of Letters in 1862; became physician to the hospitals in 1865, agrégé in 1866, Officer of the Legion of Honor in 1871, and in 1879 was welcomed into that distinguished society, the Academy of Medicine. The address in medicine at the International Medical Congress, London, 1881, was to have been delivered by Raynaud, the subject being "Skepticism in Medicine"; but the privilege was denied him, for he died suddenly from an organic heart disease on June 29, 1881. However, his friend, M. Féréol, read the paper to the Congress after his death. It is indeed interesting to note that when he published his celebrated thesis he was less than thirty years of age. For the degree of Doctor of Literature, he wrote two theses; one in Latin, "De Asclepiade Bithyno, Medico ac Philosopho"; the other, "Les Médecins au Temps de Molière." He was a most careful and keen observer, for nothing has been added to our knowledge of the disease which he so admirably depicted. M. Peters states that he was to be regarded in the fourfold character of physician, savant, philosopher, and man of letters.

The oldest recorded case (1629) was noted by Bernhard. A student of surgery with two companions put up at an inn, where they found that the daughter of their host, a girl of twenty-three, suffered every month from considerable pain in her fingers and toes, on her ears, and in the tip of her nose. There was also edematous swelling of the hands, feet, and face, followed by mortification of the parts, so that the ends of these having become white and dry, dropped off in little pieces, without feeling, pain, moisture, or bad odor.

Definition.—Raynaud's disease is a disease affecting principally the fingers and toes, though other parts of the body may be attacked, characterized by partial loss of sensation, passive congestion, which may finally lead to necrosis. There is no apparent disease of the vessel walls.

Etiology.—The cause of the disease is as yet uncovered and practically no progress has been made in finding the causal factor since Raynaud's celebrated thesis. The most plausible theory yet advanced is that the vasomotor center in the spinal cord is affected and the sympathetic nervous system is involved.

The disease is quite rare, and Osler records the fact that among 23,000 patients admitted to the Johns Hopkins Hospital in a period of twenty years, there were only nineteen cases. Monro estimates about one in 3,000 cases, but this figure, like that of Osler's, may be very low, for many suffer with the disease, and on being told that little can be done for it, suffer without any statistical record being made.

Women are said to suffer more frequently than men in the ratio of 62.6 to 37.4, though the cases admitted to the Glasgow Royal Infirmary in a decade were equally divided.

Any age may be attacked. The earliest recorded case was in a new born infant, the symptoms appearing six hours after birth and gradually progressing until the death of the child eight days later. The oldest case was in a woman seventy-seven years old.

A history of an hereditary influence is present in eight per cent. of cases, but the occurrence of the affection in single families is not noted.

Almost every walk of life is represented in the list, but those subject to exposure are more susceptible. A long and tiresome exposure seems to have brought on several of the cases.

Most cases become worse in winter, and there is no question but that cold will induce or bring on an attack. Sexual disturbances are no doubt involved in the causation of this unusual disease. Raynaud records 111 cases in females of all ages; of these ninety-three were above fourteen and twenty-six had some disturbance in menstruation.

Pathology.—The pathology of the disease is anything but definite, though the search to find the seat of the affection has been most diligent. Microscopic changes in the spinal cord have been reported in a few cases but their occurrence has not been frequent. Sclerosis of the vessel walls has been reported, but of course these are not true types, for the definition excludes such cases. Adami and McCrae believe that the spasticity of the arteries is due to the action of cold on the vessel wall, as well as reflex action. They call attention to the fact that emotion which in one individual will stimulate the vasodilators, in another will stimulate the vasoconstrictors and produce pallor. The most likely pathology is a change in the vasomotor center in the spinal cord which may be stimulated by emotional causes, poisons in the blood, or reflexly by agents acting on the periphery. The features of the gross pathology are ischemia, hyperemia, and necrosis. The fingers at first become white due to vasoconstrictor action on the terminal arteries and veins. In the hyperemic stage the color of the fingers varies from a pinkish red to a blue red and may finally become dark blue. Stagnant blood and serum are diffused into the tissues. Necrosis follows if dilatation persists, due to asphyxia of the tissue and pressure. The necrosis is superficial rather than deep.

Symptoms.—Raynaud's original description needs no improvement. The following excerpt from the original monograph is interesting. "I propose to show that there exists a variety of dry gangrene affecting the extremities which is impossible to explain on the basis of vascular obliteration, a variety characterized especially by a remarkable tendency to symmetry, since it always affects similar portions of the body, the two upper extremities, the two lower extremities, or all four at the same time. In certain instances the nose and ear are also affected. I shall seek to prove that this kind of gangrene has as its cause a disturbance of the innervation of the capillary blood vessels."

The symptoms are divided into three classical stages: (1) Local syncope, (2) Local asphyxia, (3) Symmetrical gangrene.

In the stage of local syncope one or more of the fingers or toes feel dead, and this may be accompanied by pain and cramp. The sensations are blunted and the patient often cannot tell a coin by its feel or be certain when he is counting paper money whether he has one or two dollars between his fingers. This condition may last from a few hours to a few days and then return to normal.

The characteristic features of the stage of local asphyxia are: the attacks are paroxysmal, they are recurrent and involve symmetrical parts. The fingers are dusky in appearance and all the fingers are not usually involved to the same degree. The coloring of the skin varies from a light reddish purple in mild cases to a dark bluish black in the more severely affected. Severe pain is usually present and the attack may last from a few weeks to a month and then disappear.

The stage of symmetrical gangrene is not present in all cases. Then again, it may involve only very small areas or may extend over the entire hands and feet. The fingers and toes are greatly swollen, the pain is excruciating and small areas of the skin may slough off. The hands or feet appear quite necrotic, though the process looks worse than is actually the case, for when the process abates the parts may return to quite a normal condition. The bed of the nail is often involved and becomes quite brittle.

Diagnosis.—In 1837 M. Victor François of Mons, in his "Essai sur la Gangrène Spontanée," stated that "everything concerning spontaneous gangrene, is in a state of distressing uncertainty," and to be sure his statement is still applicable. The disease must be differentiated from the following conditions:

Chilblains. The differentiation is most difficult because the two processes so closely resemble each other, but Raynaud's persists while chilblains abate and recover. Also, chilblains are not symmetrical.

Senile Gangrene. Usually only a single limb is involved. The pulsation of the artery supplying the limb is partially or totally obliterated. The artery feels hard. The deeper structures of the limb are involved. The process occurs in the aged or those affected with arteriosclerosis. The lower limbs are more frequently affected.

Phlebitis. The condition follows a long stay in bed or an acute fever. The lesion is very painful. Improvement follows rest and elevation of the part.

Diabetic Gangrene. Diagnosed by the history and the presence of sugar in the urine.

Ergotism. History of eating infected rye, or the patient has overdosed herself with ergot to induce abortion.

Congenital Cyanosis. Diagnosis facilitated by history. Other members of the family usually affected; the cyanosis increases under effort; there is shortness of breath and the physical signs of a heart lesion are present.

Arteritis Obliterans. The feet are involved much more frequently than the hands; the condition is nonparoxysmal; it is progressive in character and does not involve the parts as symmetrically as Raynaud's.

Hysterical Gangrene. The upper limbs and trunk are usually affected while the fingers are usually free from any necrosis. There is evidence of the use of phenol or some other escharotic chemical by the patient. Females desiring sympathy are usually affected.

Embolism. The symptoms come on suddenly and rarely are the extremities symmetrically involved. Usually evidence is present of valvular heart disease.

Peripheral Neuritis. The pain is along the course of a single nerve or affects the area supplied by that nerve.

Treatment.—To care for a patient suffering from Raynaud's disease means an expenditure of time, effort, patience, and indulgence. It is best to explain to the patient that results are slow and one should not become weary if, after the first month of treatment, only slight improvement is seen. The prophylactic treatment consists in avoiding undue exposure to cold.

Local Treatment. Prevent loss of heat from the part by wrapping in cotton or wool. Relieve pain with salicylates internally or preferably small doses of opium. Local circulation may be stimulated by applying the band of the blood pressure apparatus above the affected part and producing constriction for five minutes. On releasing the pressure, there is often a great deal of improvement. Another effective means of stimulating local circulation is to place the limb in a basin of tap water and attach the negative pole of the galvanic current thereto. The positive pole is applied to the spine. If there is considerable abrasion, warm fomentations of tincture of opium, glycerin, and belladonna are applied. Where there is considerable destruction of tissue, surgical methods may be employed; but one should never be in haste, for remarkable improvement has followed in cases where it seemed the parts were certain to die. Amputation should be resorted to only in the most unusual cases.

Many general measures have been employed, but only a few have yielded any results. Regulating the diet seems to have no effect on the course. Short, in 1897, recorded great improvement with the use of thyroid extract. Harrower obtained similar results in several cases by employing thyroid therapy, and I have successfully treated a case by the same means. Raynaud advocated the use of galvanism, on the basis that the disease was due to an involvement of the sympathetic. Evidence certainly seems to point in this direction. He placed the positive pole over the spinous process of the seventh cervical vertabra and the negative over the lumbar spines. In some cases he obtained good results; in others he failed. The rule for therapeutic measures in Raynaud's disease is that a measure which is highly successful in one case will not respond in another. The results that Raynaud obtained from galvanism were satisfactory and constant. The cry went up, then as well as now, by those unfamiliar with this method of treatment that the success was due to a psychic suggestion. The manner in which he answers his critics is indeed interesting. "Such is the second case of cure obtained by means of the continuous current. In connection with the first it appears to me of a nature to call for the most serious attention of the practitioners of this therapeutic measure. It would be absurd to suggest that the improvement obtained was a mere coincidence.

In both cases the malady was of several months' standing at the time when treatment was commenced and seemed to have no tendency to disappear spontaneously. In both cases also the electrical treatment was not complicated by the employment of any other means; it was followed by an immediate improvement. Hence there is no question here of one of those approximate coincidences which so often leaves the mind in doubt when one wishes to estimate impartially the value of a therapeutic agent. The first application was followed immediately by a notable alleviation. This alleviation was greater after the second than after the first, greater after the third than after the second, and so on to complete cure. Chance is very powerful, but one will acknowledge that it hardly proceeds with this regularity." The positive pole was applied over the seventh cervical vertebra and the negative over the lumbar spine; or the spinal area may be treated from the cervical fifth to the cauda equina. Another method is to apply the positive pole to the axilla over the brachial plexus and the negative over the fingers. The time of treatment is ten to fifteen minutes.

The alimentary tract should be cleared of any possible noxious substances. A good nerve tonic should be prescribed so as to prevent overaction of the vasometer center in the cord. Coffee and tobacco should be restricted or eliminated. If anemia exists iron should be prescribed. Amyl nitrite is of little value except when associated with angina pectoris.

Case History.—Mr. X. is an apparently husky man of the short and stocky type, weighing 150 lbs. He is forty-one years old, though he looks much younger. His family history is most interesting. The facts concerning the marriage of his mother are quite mysterious. When she was seventeen years old, the woman whom she supposed to be her mother, died. Shortly afterward her father suggested that she marry him, which she refused, knowing that a daughter could not marry her father. The father then told her that she was not his real daughter, but only an illegitimate child. This explanation was accepted and though she was married by a minister she can show no marriage certificate, neither can she explain the reason therefor. The patient has two brothers and they are usually suffering from some minor ailment.

The personal history of the patient, though interesting, throws no great amount of light on the possible cause. Mentally he shows no marks of brilliancy and in his conversation is very brief and talks but little. He cares little for the company of others and is rather secretive. His present occupation is that of a secretary, which necessitates much stenography. He makes little advancement due to lack of initiative. He has been married four years, but has lived with his wife for only two years because of incompatibility. He led his wife into marriage on the strength of promises he has not been able to keep.

Physically the patient has no more initiative than he has mentally. He lacks "pep" and likes to remain at home most of the time. The heart is slightly enlarged with a soft systolic murmur at the apex, but this is fully compensated for. Urine examination shows some granular casts. Blood pressure is 115 mm. Hg. systolic, and 90 mm. Hg. diastolic. Wassermann negative. Several pus pockets located in molar teeth. Blood negative. Reflexes normal. The fingers of both hands are enlarged, swollen, sensitive to touch, and of a rusty red coloration. All these symptoms have been gradually increasing during the past week. The first symptom that the patient noticed was two weeks ago, when his fingers became quite sensitive after using the typewriter for a short time. The tenderness increased and then the discoloration appeared, at first underneath the finger nails and later spreading to the rest of the fingers. The large toe of each foot is swollen, tender, and discolored and there is a small excavation about four mm. in diameter on the large toe near the nail, from which there is oozing a clear serous substance. The slightest touch of anything to this area is perceived as excruciating pain. The patient sleeps in a chair because he cannot bear to have anything touch his foot. He has slept but little for the past three nights. Salicylates have no effect. Powdered opium afforded relief. There is also a small necrotic area on the lobe of the right ear, which has destroyed the ear substance through its thickness over an area the size of a split pea. This site is sensitive, but can be touched. Two years ago the patient noticed his feet became suddenly red, but thought it was due to poison in the dye of his socks.

The first effort was to relieve the pain and to close up the oozing surfaces. The toe was placed in a solution of water through which was allowed to flow a positive galvanic current. After five minutes of this the pain was relieved and then ten per cent. silver nitrate was applied. The hands were immersed in a positive galvanic solution. Though the pain was relieved by this procedure, the swelling did not subside. In the meantime the patient had consulted two other physicians and was told that the prognosis was very poor.

My ingenuity was now on trial. After studying the patient thoroughly the idea struck me that he was of the hypothyroid type. His dry skin, stunted mentality, stunted growth, and thin, dry sparse hair were the indicators. I gave him capsules of ¼ grain each of thyroid gland, ferrous iodide, and nucleinic acid with calcium. The first day three capsules were ordered and increased one a day until there was an acceleration in the pulse rate. This occurred when the patient was taking six capsules a day. The infected teeth were removed and the dental caries was found to be quite extreme. The patient was kept on six capsules a day for a week and then reduced to five capsules a day for a week. The next week he took four capsules a day, and finally three a day. After the first week the patient could sleep without a narcotic and the fingers were less tender. The swelling began to recede and the excavation in the ear commenced to fill up with normal tissue. The improvement was so marked that the patient was sent to the country for a month's vacation. While away he took three capsules a day for a week and quit. I saw the patient the day after his return from the country and both of us were pleased with the result. The fingers had returned to their normal size and there was only the faintest trace of any red coloration. One month later the patient's fingers began to be sensitive and tender, and in order to guard against any recurrence the thyroid capsules were ordered, one three times a day, and within a week this condition disappeared. The man has been in good spirits and health since that time, which was three months ago.

The thyroid therapy did more in this case than relieve a troublesome condition. The patient has more "get-up" about himself and feels happier and brighter than he did before he commenced treatment. His wife states that he is much more alert and active and not so introspective. The writer is not possessed with the idea that organotherapy will cure all the ills of mankind. Thyroid therapy was chosen because the patient was regarded as an entity. One look at the patient and you would be struck with the idea that he was of the sleepy type, half awake, half asleep. Raynaud's disease cannot be due to a local condition because of the widely distributed areas that are affected in parts of the body that have no apparent connection. Apparently it must be a substance that circulates in the blood that can affect the ear and the finger at the same time. The most likely conclusion is that the toxin affects the sympathetic nerve fibers because the sympathetic controls vasodilatation and vasoconstriction. First the toxin stimulates the constrictor fibers, later the dilator fibers which accounts for

the passive congestion. The sympathetic and the endocrine glands are intimately related, and this fact, together with the clinical picture of hypothyroidism that the patient presented, led me to choose thyroid therapy as the remedial agent.

THE REDEMPTION OF INTERNAL MEDICINE WITH REFERENCE TO IMPROVED THERAPEUTIC APPLICATION.

By WILLIAM C. K. BERLIN, M.D.,

DENVER, COL.

Therapeutic nihilists were created through the failure to obtain remedial action of alleged therapeutic substances when applied orally or through the gastrointestinal (alimentary) tract for pathological conditions remote from or beyond this area. The reason for this failure is obvious when one considers the complexity of the enzymotic and chemical digestive processes on remedial substances so administered.

Corrective treatment of pathological conditions of the alimentary system should be confined to the oral exhibition of such therapeutic agents as will have a remedial action on this system, and possibly in conditions where the dividing line between the alimentary system and the less remote areas is not clearly defined and also in certain intermingling pathological conditions.

This subject will be discussed upon a basis of what now appears to be logical and scientific facts as regards metabolic processes and the known chemistry of the blood and tissues, in an effort to discourage further therapeutic nihilism by certain non-medical and surgical groups, who are not interested in internal medicine and who believe that the panacea of all ills lies in their trust in Providence or surgery.

For the treatment of pathological conditions remote from the alimentary tract and not intimately associated or intermingled with it, two methods of more direct scientific application of remedial substances are available. The first is the subcutaneous and intramuscular application of remedial substances.

The subcutaneous and intramuscular application of therapeutic substances for diseases remote from the alimentary tract is much more direct than the oral application; much quicker in action, and with a greater assurance that more of the active principle of the preparation so administered is utilized.

On the other hand, many substances when injected beneath the skin or into the body of a muscle cause pain which, in itself, limits the freedom of using this method of application; and also, while they are more rapid in absorption and distribution than when given by the mouth, yet if such substances be in a state of incompatibility, chemically, with the tissues so injected they are liable to cause induration and possibly necrotic areas or to be permanently encapsulated; especially is this true if such substances are in a high degree of concentration.

Another objection, however, is the reversed osmotic process on which these substances must depend for their entrance into the blood stream and final distribution to remote areas. To obviate these objections, the third or more scientific method of direct application is the placing of remedial agents directly into the circulation (intravenously).

Before discussing the advantages or disadvantages of this latter method of therapeutic administration, let it be understood that there is little doubt that the members of the medical profession at large are in accord with the opinion of the Council on Pharmacy and Chemistry of the American Medical Association, in the propaganda against the indiscriminate use of the vein for the administration of therapeutic substances. This, of course, cannot apply to carefully selected remedial agents which have been converted into a state of chemical harmony with the blood.

The blood is a highly organized complex chemical fluid which is capable of converting many remedial substances to its own metabolic use and rendering others innocuous for its own protection. By the intravenous application of substances, when rendered chemically compatible with the blood, it is immediately converted into a state in which it may take its place in the general scheme of metabolism, and when it finally enters the various tissues it is by a direct osmotic action; in other words, the blood is carrying constructive anabolic material as well as remedial substances, and these are delivered by direct osmotic action to all the cellular tissues of the body.

For pathological conditions remote from the alimentary tract the direct application of remedial substances seems, according to this view, to be more effective and less objectionable than other modes of application. This is particularly true in pathological conditions intimately associated with, and readily accessible through, the blood stream; furthermore, through osmostic processes these remedial substances are carried into the more inaccessible areas, as, for example, the cerebrospinal tract. This process is admirably demonstrated by Osborne[1] in the quantitative estimation of iodine in the cerebrospinal fluid before and after oral, rectal, and intravenous administration of sodium iodide; demonstrating that the amount of sodium iodide found in the cerebrospinal fluid after administration by mouth or rectum is small compared with that following intravenous administration.

Accepting these statements as true, the chief requisite to accomplish the safe application of remedial substances through the circulatory system is an intelligent understanding of the chemistry and the proper chemical adaptation of these substances to the blood, and in order to avoid the use of prepa-

rations of questionable compatibility with the blood it is necessary to follow those who are fitted by experience to test the chemical, physiological, and therapeutic action of such substances *in vivo*.

Of the two methods of application for pathological conditions remote from the alimentary tract it is obvious that the venous is the more scientific and effective. Undoubtedly many medicaments must be classed as unsuited for intravenous use on account of their insolubility or chemical incompatibility. This chemical antipathy is shown in reactions expressed by different grades of vertigo, vasomotor stimulation or depression such as flushing or pallor of the face with evidences of shock of varying degrees up to and including the true anaphylactic state.

For example, the injection of the acid salts of quinine, such as dihydrochloride, frequently causes pallor and dizziness. This is not generally true of the neutral salts such as the cacodylate. The danger of reaction and anaphylaxis through the intravenous application of these agents is, however, no greater generally than when they are administered orally. Then, too, the chemistry of the blood in certain individuals differs from the normal, the blood in such individuals being chemically intolerant to substances generally accepted as compatibles with the blood of the masses.

It is of interest to note the celerity with which favorable results are obtained by the intravenous application of the iodine preparations in pulmonary[2] disturbances. In these cases the intravenous administration constitutes the most direct application to the lungs possible,[3] the course being through the veins to the right heart, thence by way of the pulmonary arteries to the lungs.

Diseases of the kidneys, which are now considered generally as of an infectious origin,[4] as well as those of the entire urinary tract with their intimate association with the blood stream, are quite accessible to the intravenous application of remedial agents.

Pyelitis has been in the past a difficult condition to control successfully by means of the oral administration of remedies, but there is sufficient evidence at hand to warrant the intravenous application in these conditions with the assurance of immediate results.

Recently a number of cases of this type have been treated in this manner. Three cases, immediately in mind, occurred in two women and one female child nine years of age.

In the first case the patient was passing 50 per cent. centrifugal pus from the left kidney pelvis accompanied by pain and temperature ranging from 101° to 103°. The preparations were applied intravenously; the base of one was hexamethylenamine, alternating with a compound of sodium hypoiodite, sodium orthocreosote, and sodium guaiacolate. In this case the temperature was normal preceding the third application, with pain relieved and pus 3 per cent. centrifugal; complete recovery, however, was rather prolonged.

The second was a mild case of chronic arthritis complicated by pyelitis and a mild nephritis showing about 10 per cent. serum albumin and an additional 1 per cent. of nucleoalbumin. In addition to these complications there was present a mild type of cholecystitis with a mild icterus and considerable edema of the extremities. A month's application of the same preparations given every other day was sufficient to clear up the jaundice, edema, and pus, and bring about a decided improvement in the arthritis.

The third was a case of a year's standing beginning with frequent and irritable urination and ending, finally, with complete inconstancy of urine carrying 45 per cent. pus (centrifugal). Oral administration of drugs as well as the subcutaneous use of autogenous vaccines and the local treatment of the bladder and pelvis of the kidney failed to influence the course of the disease. Hexamethylenamine and the hypoiodite preparation were given intravenously every second day alternately for a short period, after which the hypoiodite preparation was used exclusively for a time, then the interval was lengthened to every other day. At the end of twenty-four hours after beginning treatment the centrifugal urine gave a reading of 9 per cent. pus. As a result of another injection at a twenty-four hour interval the pus fell to 3 per cent. and the bladder in the meantime had resumed its normal function. In a very short time the child had recovered sufficiently to resume her attendance at school.

The same favorable prompt action of preparations of which iodine in some form is the basis is exhibited, in a most constant manner, in certain forms of asthma, bronchitis, and pneumonia, and in the mixed type of infection complicating pulmonary tuberculosis.

Finally, there is a strong possibility that the work of Osborne will prove true for substances other than sodium iodide, such as preparations carrying the different salts of arsenic, mercury, and iodine, either alone or combined, as has been demonstrated clinically in the treatment of locomotor ataxia and other pathological conditions of the central nervous system.

Should these opinions be substantiated in time by others working along this line, then the intravenous application of remedies properly adapted to and rendered chemically compatible with the blood will find their way, probably through the arachnoid membrane and cells by osmosis, into the cerebrospinal fluid more promptly than when applied in any other manner except by spinal puncture directly; however, spinal puncture is subject to so many well deserved objections that it may very probably become obsolete and will not be practised except for diagnostic purposes.

Résumé.—1. It would seem logical to reserve the oral administration of remedial substances for pathological conditions of the ailmentary tract and its anexa.

2. It would seem equally logical to reserve the subcutaneous and intramuscular application of remedial substances for pathological conditions remote from the alimentary tract.

3. It is without doubt logical to utilize intravenous methods for pathological conditions remote from the alimentary tract and readily accessible by the blood stream, either directly or by osmotic processes, and especially in reaching therapeutically otherwise inaccessible areas.

FRACTURE OF THE NECK OF THE FEMUR.

A Report of Three Cases with Delayed but Successful Application of the Whitman Abduction Treatment.

By S. KLEINBERG, M.D., F.A.C.S.,

NEW YORK.

It is admitted by most surgeons today that for a recent fracture of the neck of the femur the Whitman abduction treatment is the most effective method and offers the best opportunity for complete healing with return of good function. The success of this method is due to the fact that it includes the two essentials for healing in all fractures, namely, proper alignment and contact of the fragments, and effective immobilization. In long standing cases where the fracture has existed for months or years, some form of operative repair is necessary to obtain a satisfactory functional result. There is, however, a group of cases seen from one to six months after the injury in which healing has not taken place; marked absorption of the femoral neck is as yet not apparent and there are persistent pain and disability. In these cases, most surgeons, believing non-union to be inevitable, advise bone pegging, nailing, Bracket's operation, Whitman's reconstruction of the hip, and various other operative procedures. I have recently had three such cases in which the application of the Whitman abduction treatment, used in the classical way, has given complete union and cure.

Case I.—J. M., male, 34 years old, was referred to me by Dr. Williams on Sept. 20, 1918. Four months previously he had fallen and sustained a fracture of the neck of the right femur. He was taken to a hospital where a plaster of Paris bandage was applied. the splint was left on for 7½ weeks, after which it was removed and the patient was encouraged to walk. When he came to me he walked with the aid of crutches and complained of pain in the right hip and marked weakness of the right lower limb.

Examination showed that the right lower limb was 1⅛ inches shorter than the left, the limb was in moderate outward rotation, the great trochanter was elevated above its normal position, abduction and inward rotation were entirely restricted and *x*-ray examination showed a typical fracture of the neck of the femur. The fracture line was distinctly visible and passed through the neck near the great trochanter. The angle between the neck and shaft was reduced to about 100 degrees. There was evidently no union of the fracture. My intention in this case was to drill a hole in the great trochanter and the neck of the femur and insert a graft according to the method advised by Dr. Albee.

On account of the comparative youth of the patient, and at the suggestion of Dr. Charlton Wallace, I decided to try the typical Whitman treatment. The patient was given a general anesthetic, and by manipulation the limb was pulled down and brought into a position of marked abduction, inward rotation, and complete extension. In this position a plaster of Paris spica bandage was applied extending from the nipple line to the toes. A subsequent *x*-ray showed that there was practically perfect alinement of the fragments with reestablishment of the normal angle between the neck and shaft. The spica was left on 4½ months. When the plaster was removed the fracture was found entirely healed, the head of the femur moved with motions of the shaft, the deformity had been entirely corrected, and the sensitiveness of the hip had completely disappeared. The fracture was evidently healed. Another short plaster of Paris spica was applied from the nipple line to the knee. Seven weeks later the plaster was removed. An *x*-ray examination at this time showed that there was an abundant callous formation at the site of fracture. The fragments were in good alinement. He was now able to bear weight on his limb without any discomfort, although he was encouraged to walk about only with the aid of crutches. A third short plaster of Paris spica was applied to assure fixation of the hip. This was removed seven weeks later, when it was found that the fracture was firmly healed. He had no pain or sensitiveness of the hip. The limb was in about 15 degrees of abduction, and in complete extension. He was able to flex it to about 120 degrees and there was some rotation in both directions. All motions were painless. Six weeks later a note was made that the fracture was entirely healed, that he was able to walk comfortably without effort and without any support.

Thus, by the use of the classical Whitman abduction method of treatment applied in this case four and a half months after the injury, complete healing of the fracture and restoration of function were obtained within a period of a little over nine months.

Case II.—Mrs. T. K., age 65, sustained a fracture of the neck of the left femur. She was treated with a short plaster of Paris spica for five weeks and then was encouraged to walk. She was given massage and manipulation. The pain and disability in the left hip steadily increased and five months after the injury she was referred to me.

Examination by me on June 5, 1920, showed that she was in good general condition, but was unable to walk without crutches. The left lower limb was in an attitude of outward rotation; there was prominence of the great trochanter and evident shortening of the limb. The left limb was 1¼ inches shorter than the right. An *x*-ray examination showed a fracture apparently at the base of the neck of the femur. The angle between the neck and shaft was reduced to a right angle. The line of fracture was plainly visible and there was a distinct gap between the head and the great trochanter. The gap was, however, not very wide and instead of an operative reconstruction or repair of the fracture, it was decided to apply the Whitman abduction treatment.

The patient was anesthetized, the limb stretched and manipulated and brought into a position of complete extension, inward rotation, and abduction of 20 degrees. In this position the limbs were of equal length. A long plaster of Paris spica was applied.

An *x*-ray picture taken through the plaster showed practically normal relation between the head, neck, and shaft of the femur. It is interesting to note that while in the original picture the head of the femur seemed to be practically in contact with the great trochanter as if the neck had been absorbed, in the second picture the neck was completely visible indicating that there had been a rotation of the fragments which obscured the presence of the neck.

About one month after the plaster had been applied the patient complained that she felt something slip in her hip and when a subsequent *x*-ray was taken, it was found that the shaft of the femur had slipped up a little. On August 10, 1920, the plaster was removed and the head of the femur was found to be moving with motions of the shaft. There was no longer any tenderness of the head, neck, or trochanter and, clinically, the fracture seemed to be healing. By measurement the left lower limb was ½ inch shorter than the right so that there evidently had been some slipping.

An *x*-ray picture taken at this time showed that the line of fracture was still distinctly visible. It also showed the upward displacement of the femur and that the lower border of the fracture line on the inner aspect of the great trochanter was ½ inch above the corresponding border of the neck. Nevertheless, there was good alinement of the fragments and the radiographer thought there was increased density of bone at the line of fracture, indicating healing. Another plaster spica bandage was applied and this was allowed to remain on two months. When it was removed the fracture was found healed and the alinement satisfactory. The patient was kept lying in bed for two months more, receiving baking and massage and manipulation to maintain abduction. She was then permitted to walk

about with crutches but bearing no weight on the injured limb. At the end of six weeks she began to bear a little weight on the injured limb and since then has progressed very favorably.

Examination on April 30, 1921, 10½ months after the application of the Whitman abduction treatment, showed that she was in good general condition. She was able to walk without the aid of crutches and bear a good deal of weight on the injured limb. The fracture was healed, although there was ½ inch shortening of the limb. When lying in bed she was able to elevate the limb demonstrating that she had good control of it.

In this case, seen five months after the injury, the fracture was treated by the abduction method and a satisfactory result was obtained.

Case III.—J. N., 69 years old, sustained a fracture of the neck of the left femur on July 6, 1920. He was admitted to the Hospital for Ruptured and Crippled on August 12, 1920, with the typical symptoms of fracture of the neck of the femur. An *x*-ray picture showed a fracture through the neck with upward displacement of the great trochanter and reduction of the angle between the neck and shaft to a right angle.

At the time of his admission the question arose as to whether we could be successful with the application of the usual Whitman abduction method of treatment or would an operation be necessary to obtain a cure? I decided to use the conservative method of treatment as follows: On August 16, 1920, the patient was given a general anesthetic and the affected limb was manipulated and brought into a position of 30 degrees of abduction, complete extension, and moderate inward rotation. A long plaster of Paris spica was applied from the nipple line to the toes. An *x*-ray picture taken through the plaster showed a very distinct improvement in the position and the relation of the fragments.

Three months later the plaster spica was removed and the fracture was found to be clinically healed, that is, the head of the femur rotated with motions of the shaft. An *x*-ray picture at this time showed that the fragments were in apposition and in good alinement. A short plaster of Paris spica was applied and two months later it was removed. Examination showed that the limbs were of equal length, the hip was not at all painful, and the fracture was healed. The patient lay around in bed for another month, receiving baking, massage, and manipulation, the latter directed to retaining a fair degree of abduction. He was then permitted to get out of bed with the aid of two crutches bearing weight only on the unaffected limb. On March 31, 1921, 7½ months after his admission to the hospital, there was firm union and the patient was able to walk with the aid of only a cane.

This case demonstrates again the possibility of obtaining complete healing with the Whitman abduction method of treatment, even when it is applied some time after the hip was fractured.

The results obtained in the foregoing cases show that in ununited fractures of the neck of the femur, the Whitman abduction treatment may be applied even as late as five months after the injury with the expectation of complete healing and cure. It must be emphasized that we do not believe the abduction treatment to be applicable to cases of non-union in which there is marked absorption of the neck and upward displacement of the shaft. The cases here reported differ from the ordinary long standing case in that there was very little absorption of the neck, and that the interval between the neck and the shaft was still small and could be obliterated by the manipulation required by the technic of the abduction method. It is my belief that in these cases, more than in the fresh fractures, *proper* manipulation is indispensable for a good result, for it establishes contact and favorable alignment of the fragments. The contact is assured by the position of abduction. Several blows with a mallet over the great trochanter, as advised by Dr. Cotton, serves to irritate the fractured surfaces, increases the degree of contact, and favors healing. The immobilization should be as prolonged as in a recent fracture.

A FEW THOUGHTS ON PROSTATIC DISEASE.

By A. WIESE HAMMER, M. D.,

PHILADELPHIA, PA.

In presenting the thoughts expressed in this paper, the writer is more actuated by a desire to keep in mind some of the more salient factors upon this important subject, than to offer anything of a unique nature.

One fact stands prominent at the very gateway of approach and that is that urinary diseases, especially those that fail to respond to the usual therapeutic measures and are chronic in nature, ofttimes find their etiology in prostatic involvement.

It is not our province to dwell upon the nature of the prostate, to digress upon its topographical relations, or to add the more common facts described in textbooks, except to call attention to the misnomer so universally applied and so generally employed, namely, "hypertrophy" of the prostate. The process is anything but a true hypertrophy, for it occurs at a time of life when atrophy and not hypertrophy is taking place. This so-called hypertrophy involves only certain parts of the gland, and if the term is to be applied at all, it should be clearly indicated in what parts of the gland the pathological tissue originates. This is a most important consideration, for upon a correct appreciation of these processes—adenomatous in character—is to be determined the most effective method of attacking them.

Anatomically considered, the prostate is divided into a posterior, a median, and two lateral lobes. Albarran emphasizes the fact that occasionally the anterior lobe of fetal life persists as well as some detached groups of glands. Recent investigations make it evident that the adenomatous masses arise from the median and from the lateral lobe and rarely from the persistent subcervical glands or a persistent anterior lobe, *but there is no evidence that they ever arise from the posterior lobe.*

The investigations* and studies of many British scientists and surgeons, including the brilliant observations of Mr. Thompson Walker, indisputably prove that the nature of the coverings of these adenomatous masses vary according to the different parts of the gland which are affected. Thus the masses occupying the lateral lobes are covered posteriorly by the posterior lobe and do not here come in contact with the capsule of the prostate. Laterally, they lie against the capsule of the prostate; superiorly, they abut upon the median lobe, while mesially they are covered solely by mucous membrane and by the stretched and atrophied capsule of the prostate, from which they cannot be separated by dissection even after removal from the body.

If the adenomatous mass arises from the median lobe, it is covered posteriorly by the posterior lobe

*"Suprapubic Prostatectomy," by Hugh Cabot, *Surgery, Gynecology and Obstetrics*, August, 1913, pp. 213-217.

and as its overgrowth takes it backward it comes in contact to a greater or less extent with the neck and wall of the bladder. Laterally, it borders upon the lateral lobe; anteriorly and superiorly, it is only covered by the thin, atrophied mucous membrane from which it cannot be separated or dissected.

The posterior lobe of the prostate lies wholly behind the ejaculatory ducts, thus forming part of the floor of the urethra. The sides of the prostatic urethra are formed by the lateral lobes, and the floor from the verumontanum to the orifice of the bladder by the median lobe.

Thus, in enucleating, by the intraurethral method, the mucous membrane tears at the sides, at the junction of the floor and the lateral wall up to the verumontanum, at which line it tears transversely following the line of the median lobe. Thus the undeniable fact—that by this method of enucleation the posterior lobe and its structures, especially the ejaculatory ducts, are left undisturbed.

Based upon these facts, it is evident that although such authorities as Mr. Freyer and Mr. Thompson Walker, the English surgeons, assert that in enucleation the entire prostate is removed, such a procedure would include removal of the posterior lobe, with portions of the ejaculatory ducts. Specimens preserved for observation and study never evidence the presence of these structures. In other words, what actually occurs in these operations of enucleation is that the adenomatous masses in the lateral and median lobes are shelled out from the capsule of the prostate at the side, from the muscular structure of the bladder neck above, and from the posterior lobe (the old so-called surgical capsule) below.

As was mentioned earlier, all urinary affections demand a thorough examination of the prostate. Thus, in so-called hypertrophy, the symptoms of the first stage are mainly dependent upon the condition of congestion in the prostate, bladder, and kidneys. And as this congestion is most considerable in the prostate, the most noticeable symptoms caused by it are disturbances of micturition and of sensation, due to the irritated state of the neck of the bladder. In the second and third stages we have in addition a series of symptoms due to mechanical obstruction to micturition, and to changes in the bladder and other organs consequent upon this obstruction.

The urinary findings are never constant. The examination may be negative, especially during the early stages of the disease. With the occurrence of congestion of the kidneys, there are evidenced albumin and casts. Later in the disease, as polyuria establishes itself, the specific gravity is low, commonly 1,003 to 1,006, and there is usually a small amount of albumin, although this may not be present. At this time a few casts are usually also found, but they may be absent even when the kidneys are seriously involved. However, with acute cystitis, the urine becomes thick from an admixture of pus and mucus, which often settles at the bottom of the vessel as a thick, ropy mass. The sediment also contains prostatic cells and many phosphates.

A word as to catheterization. Many cases are cured by it. Of course, this is applicable when the stage of partial retention has set in and the patient passes water, but is not able to empty the bladder completely. When absolute retention comes on suddenly, the catheter is indispensable, but even in these cases its use will later likely be given up.

It is to be remembered, however, that when entering upon the use of the catheter, we may learn if we are on the right track by noticing the effect upon the symptoms; but also a cystitis may develop, owing either to a too sudden evacuation of a distended bladder or to the introduction of foreign matter upon the catheter, or to irritation from constant use of instruments.

The evacuation of a distended bladder should be performed carefully and slowly. When the distention is extreme, the bladder should not be wholly emptied at one time, for if the internal pressure is too suddenly removed we are likely to find a congestion of the vesical mucous membrane, with escape of blood in the urine. The greatest care also should be exercised to follow rigidly the rules of antisepsis, for the introduction of germs into the bladder may start a fermentation of the urine with cystitis.

In what is often designated the third stage of the affection, systematic emptying of the bladder is as urgently called for as in the earlier stages; but the serious changes which are likely to have occurred in the ureters and the kidneys, plus the passive congestion which now exists throughout the urinary tract, makes the employment of the catheter a matter of serious concern, and so great may be the danger that it is better practice to leave the bladder undisturbed.

In these cases the patient's condition of comparative health makes a striking contrast with that alarming condition which may rapidly develop upon entering "catheter life." For a slight irritation of the bladder may be suddenly followed by a pyelonephritis, or perhaps even worse—renal congestion with suppression, uremia, and death. The dangers are alarming and imminent enough to make us hesitate and regard the condition with trepidation and reserve. But what good can accrue from inaction? What benefit can be attained by closing our eyes to the affection that confronts us? When catheterization is successfully accomplished, the disease may be moved back from the third to the second stage, and the patient, whose life appeared in imminent jeopardy, may again be regarded as in a state of apparent security.

Which cases, then, we may ask, are adapted to catheterization? Each of these must be decided upon the symptomatology in question. So much depends on attention to detail that we may sometimes be deterred from beginning catheterization with a careless and slovenly patient, when we should have resorted to it could we have counted on his intelligent cooperation.

Radical treatments aim at a cure. Perhaps the main reason why operative treatment has not been more generally successful in the hands of some surgeons is to be found in the age of the patients, for in the majority of cases such affections attack men between fifty and eighty years of age, and it is obvious that severe operations become more dangerous with advancing years. Individual conditions are often the governing factors in determining the advisability of operation. Social position plays a dominant rôle. A man of the lower class who cannot afford the time, trouble, and careful atten-

tion to detail necessary to make "catheter life" tolerable, may wisely be advised to have some operation performed. A man of advanced years, in comfortable circumstances, may be kept quite at ease by less radical and safer methods.

Again, so often those of a better social position are among the more intelligent, or they can secure the services of a trained male nurse or of some one who can appreciate the dangers and the trials incident to the management of catheterization, for the greatest care must be given to gentleness as well as to asepsis. Frequently after the first few days of catheterization the inflammation of the urethra manifests itself with hemorrhage after each use of the catheter. False passages not infrequently result from forced use of the instrument. Epididymitis is a not uncommon complication.

With these few selected thoughts on an all-important subject, we glance for a moment at the subject of prostatectomy. The mortality of this operation finds its greatest expression in lack of kidney function (60 per cent.). The condition is most largely brought about by the back-pressure arising from obstruction by the enlarged prostate, the patient dying of uremia. It is estimated that about 11 per cent. of fatalities are due to shock and to hemorrhage. Very remote and rarer causes of death following this operation are: Pulmonary embolism, cerebral hemorrhage, and pneumonia. It is the consensus of opinion to-day among the best surgeons that there are no contraindications to the operation.

Some surgeons prefer the suprapubic operation; others, the perineal. The average *functional* results of the suprapubic operation are, as a rule, better. General surgeons, as a class, adopt this latter method, and it is for this reason believed that the mortality is a little higher than by the perineal pathway. The perineal method is most frequently the choice of skilled genito-urinary surgeons and their long experience in this particular branch of surgery accounts, no doubt, for a lesser mortality than by the suprapubic operation. However, the fact remains that among the sum total of all operators, suprapublic prostatectomy is the operation of choice. But, as in all operations, the one best suited to each case is of first importance and it is, therefore, often wise to examine the bladder carefully with the cystoscope before deciding which operation should be undertaken, or whether any operation is likely to give permanent relief.

Mention is merely made of Bottini's galvanocaustic operation, of bilateral orchidectomy, introduced to the notice of the profession by the late Dr. J. William White, of the University of Pennsylvania, of the operation of vasectomy, of ligation of the cord, of both internal iliac arteries, etc., as measures proposed at different times by eminent surgeons for the cure of so-called prostatic hypertrophy. All of them have fallen into ill-repute. In many instances, after employment of Bottini's operation, stenosis of the vesical neck has occurred. The operations of orchidectomy and vasectomy have resulted in repeated failures; while ligation of the cord and also ligation of the internal iliac arteries are operations that many years ago proved unnecessarily severe and unwarranted.

218 South Fifteenth Street.

COMPULSORY HEALTH INSURANCE.

A CONNECTICUT VIEWPOINT.

By WILLIS E. HARTSHORN, M.D., F.A.C.S.,

NEW HAVEN, CONN.

The question of compulsory health insurance will propably be one of the important issues considered at their next meeting by several State legislative bodies. In this country the subject was first taken up by the American Association for Labor Legislation, with headquarters in New York and with about 3000 members. This association had previously been active in securing the passage of the workmen's compensation laws which have been adopted in forty-two States. In December, 1912, it organized its health insurance committee. In 1917 the bill was introduced into the Connecticut State Legislature. A commission was appointed to investigate the matter. This commission reported unfavorably.

The standard bill adopted by the American Association for Labor Legislation provides that all employees earning less than a given amount ranging from $800 to $1,200 shall be entitled to medical, surgical, hospital and nursing care, dental treatment, maternity benefits, cash benefits, and funeral expenses. These services are to be paid for out of a fund of which the State furnishes one-fifth. Two-fifths are to be contributed by the employee in the form of compulsory payments of a certain percentage of his wages, variously estimated at from three to seven and one-half per cent., and the remaining two-fifths are to be contributed by the employer. Employees receiving less than $5 per week pay nothing, the employer paying eighty per cent., and the State twenty per cent. Medical and surgical attendance is provided either by the appointment of certain physicians as whole time insurance physicians or by the creation of a panel or list of physicians in each district willing to care for those insured. Proposals for the payment of physicians also differ. One is to pay each physician a fixed salary; another is an annual pro rata division among all the physicians on the panel, of the amount appropriated for the medical and surgical services for the district; a third is a capitation series by which each physician is paid in accordance with the number of persons treated. Let us for a moment consider the arguments in favor of such legislation. The brief of the model bill prepared by the American Association for Labor Legislation claims: (1) That there is at present a disproportionately large amount of sickness among employed persons causing immediate loss of time and wages amounting each year to half a billion dollars. (2) That the wages paid American working men are inadequate to enable them to meet the expense of sickness and to bear the losses consequent on sickness and incapacity, and that it is therefore necessary to distribute this burden among three parties—the employee, the employer, and the State. Commenting on this, Dr. George Blumer, president of the Connecticut State Medical Society, writes:

> These statements are based upon statistics of a rather fragmentary character, gathered at various times and from a variety of sources. There is no direct evidence that they are applicable to the conditions found in the State of Connecticut in the year 1921. Before the ques-

tion of health insurance is seriously considered in Connecticut, accurate data covering the conditions as they exist in this State are necessary: (1) The amount of sickness among employed persons as compared with the general public must be secured. (2 The nature of this sickness. (3) The average amount of wage per year lost by each worker on account of sickness. (4) The yearly incomes of the various types of workers in the State. (5) The percentage of wage earners whose incomes are insufficient to meet the expenses incident to sickness.

In addition to these data information is also needed as to the provisions already existing in the State for the medical and surgical treatment of those unable to meet the expenses incident to sickness.

When all these data have been obtained the whole question of the best methods of correcting whatever unsatisfactory health conditions may be found should be considered without prejudice. Any promising and workable plan should be carefully scrutinized and the method should be adopted which offers the greatest hope for success with the least expenditure of public money and the least disturbance of the rights of the public and the medical profession.

The matter of compulsory health insurance should be considered in a spirit of fairness. We do not wish to go on record as opposing from selfish or financial reasons any method which will reduce sickness in the community or help the working man. The need of exact statistics covering the care of the sick poor is, however, very essential. As presented, the proposed plan is simply a method of taxing the citizens of the State, either directly or indirectly, to furnish medical and surgical service to maintain the productive efficiency of part of the population.

The American Medical Association and the Federation of Labor have both gone on record as being opposed to compulsory health insurance. It is essentially a socialistic idea. All the cost will ultimately come on the consumer and the citizen. Neither the employee nor the employer as such will bear any real part of the expense. We are not faced with any such problem as exists in England, owing to the prevalence of benefit societies. Our medical profession is probably the best trained in the world. Its personnel is of the highest possible type, with rare exceptions, considering the number of practitioners. What would happen if some such plan as has been previously outlined was adopted, for example, in Connecticut. The workman, finding that a certain amount was deducted from his wages each week, would immediately demand that they be increased enough to make good this deficit. The increased wage would add to the operating expense of the plant. The employer could hardly be expected to pay his assessments out of his profits. He would add his share to the operating account. For the reasons above stated the cost of his product would be correspondingly increased. So in the end the public pays and the high cost of living is further increased. The one-fifth contributed by the State could be paid out of the State treasury only in money secured by increased taxation of its citizens.

The proposed plan is really not insurance at all, but simply a plan for providing medical, surgical, and hospital care in order to increase the industrial output of a portion of the population at the expense of the entire citizen body through direct and indirect taxation. It is approximately estimated that it would cost the State of Connecticut two million dollars to introduce compulsory health insurance and that the annual expense, including administration, would be at least this amount and probably a good deal more.

In writing this paper information has been drawn freely from the public health series of the American Medical Association, and especially from the valuable article on health insurance and physicians written by Frederick R. Green, M.D. The concluding paragraph of this article sums the matter up as follows: It is suggested that each State, where bills are presented, request the legislature to appropriate a sufficient amount of money to enable the State Board of Health to make a complete and exhaustive study of the entire State, showing how the existing health organizations may be increased and developed to a point where every citizen of the State regardless of his economic condition or industrial status may be protected from disease and may enjoy the highest degree of efficiency.

The statement has been repeatedly made that compulsory health insurance is inevitable. There is not the slightest basis for such an assumption. It is no more inevitable than the adoption of any other proposed measure.

In New York State during the past few years the question of compulsory health insurance has received special attention. Several bills have been introduced into the legislature. Both the public and the profession, through a campaign of education, were informed regarding their fallacies. They failed to pass and this in a State where socialism has many adherents.

Each physician should cooperate in every way with the committee of the State Medical Society in informing the public and the profession regarding the exact status of compulsory State insurance. The chairman of the Connecticut State Committee considers it very essential that each physician make a thorough investigation of the matter. It would perhaps be wise for the County Associations to issue a short pamphlet containing the needed information or to send a copy of Dr. Green's article in the Public Health series to the members, thus stimulating their interest in this important matter.

SOME REMARKS ON THE USES AND ABUSES OF PITUITRIN IN OBSTETRICS.

By I. JOSEPHSON, M.D.,

NEW YORK.

So long as the general practitioner continues to accept the care and treatment of the parturient woman this branch of medicine will continue to remain a thorn in his otherwise not too roseate existence. Time and the stork wait for no man, and while the necessity remains he will endeavor to find ways and means of accommodating himself to the irregularities resulting therefrom. In spite of the various newfangled ideas which have from time to time arisen in his efforts to lighten his burden and in his attempts to alleviate somewhat the suffering incident to labor, from the beginning of the history of medicine up to and including the recent popular but short-lived twilight sleep, the obstetrician today is just as powerless in these respects as he was at the start, and no doubt will remain so till the end of time.

Although the physician has made great strides

in his management of the abnormal or complicated confinement case, the so-called normal or uncomplicated case must be left to nature to take care of as she will, in spite of the inconveniences which are often the lot of the physician in conducting the same. Mealtimes are upset, sleep is disturbed, vacations are interfered with, and the normal routine of life is not of the smoothest. As we cannot control Nature's whims, and since the physician knows that he will be required to make these sacrifices, he must either be willing to submit to these irregularities or leave this branch of medicine strictly alone. Any effort on his part to shorten the labor by injudicious means in order to save time, such as the unnecessary application of forceps or the hypodermic injection of drugs when no other real reasons for these procedures present themselves except pressure of time, cannot but be accompanied by a considerable amount of danger.

It is against the indiscriminate use of pituitrin for this purpose and to point out that like any other drug it has its indications and contraindications that these lines are written. It is true that the literature on the value of pituitrin in obstetrics is voluminous and it would seem as though any further remarks on the subject were superfluous; that this topic has been fully discussed and that the application of this drug is thoroughly understood by the average practitioner. But we know that this is not the case, for the ruptured uterus and stillbirth after its exhibition are still heard of only too frequently. In view of these facts, a few more words added at this time will not be out of place.

I happened recently to glance casually through the book kept in the delivery room for the entry of medication during labor in a maternity hospital while I was at the time waiting for a private case of mine to deliver herself, and was surprised to note the frequency with which the entry "Pituitrin 1 c.c." was made after the names of many of the patients delivered by private physicians. I was induced, as the result of this discovery, to make some inquiries among some medical friends with a view to ascertaining how and when this drug was used in the routine of the average obstetrical practice. The most surprising result of this investigation was the admission by most of the men interviewed that they were in the habit frequently of administering pituitrin when pressed for time in cases that were progressing uneventfully. By shortening the labor in this way they were enabled to keep other appointments or to attend their office hours on time, when they found that the labor if not terminated in some fashion would interfere with their other work. It would, therefore, not be amiss to review briefly the acknowledged indications of the present-day uses of pituitrin in order further to impress upon the physician that we are dealing with a drug that cannot be respected too highly and which must be handled with the greatest care.

Pituitrin to-day is used most frequently in the following instances: Firstly, in uneventful labors after full dilatation, with the head on the perineum, when it seems all will be over with a few more pains, but the uterus suddenly gives up and refuses further to contract. A small dose will often in such a case produce the few necessary contractions to complete the delivery. Secondly, to increase the force of the contractions in a slowly progressing tedious labor, a small dose of four or five minims administered at intervals depending upon the progress of the case will increase the force of the uterine contractions and so shorten the labor. Third, it is often used as a preliminary to the application of forceps, the object being to force the head more securely into the pelvic canal in order that the delivery may be facilitated. Fourth, during cesarean section it is a common procedure to administer an ampoule of pituitrin before the uterine wall is incised, the object being to have the uterus contract firmly by the time the placenta has been extracted and the uterus is being sewn up. The fifth and the most important use of this drug I will discuss later.

We will concede that in all the instances cited it has acted like a charm, as it often does, and were it always to do what we expect of it, nothing further would need to be said on the subject. But there are few drugs that are so protean in their action as pituitrin, as any physician who has had the least experience with it will admit, and because of its uncertainty in its action in the most carefully selected of cases it is a dangerous drug to use in any instance. We often find that it will, in some cases, when injected, produce powerful contractions within a few minutes and if any unrecognized maternal or fetal dystocia be present dire consequences may ensue; at other times it will produce no effects until half an hour or more has passed; and finally it frequently fails to have any action at all. Also we are occasionally apt to find our disappointment upon its failure to act increase to chagrin on being confronted by a stillbirth, after delivery finally takes place, which we cannot trace to any other source but to the injected pituitrin.

However, we are none of us infallible, and it is not my purpose or desire to pick any bones with the physician who uses pituitrin after careful thought and with an honest conviction that it is indicated in the particular case in which its use is contemplated. My main objection is the practice of exhibiting this drug which has such powers for evil as well as good, a drug that is dangerous to use at its best, for otherwise but strictly legitimate reasons and not as a valuable adjunct in the saving of time. To repeat, the practice of obstetrics must of necessity consume a great deal of the physician's time, and unless he is prepared to devote the required time he should not accept the confinement case at all.

I believe I have made it plain, however, that not only do my objections to the use of pituitrin include those instances where it is given unnecessarily, but I personally believe that it should be withheld even where its use is sanctioned; and when I have my choice between forceps and pituitrin I always choose the former, for I can manipulate the forceps at will, but once the drug is in the system it is beyond our control.

When, then, shall we use pituitrin? There is one and only one legitimate use for pituitrin and that is in post-partum hemorrhage, either as a prophylactic or in the actual treatment. Used for this purpose only, there is sufficient excuse for its eminent position in our medical armamentarium. While the fetus is still in utero its use, no matter

how favorable the conditions, is always fraught with more or less danger. Once the child is on this side of the world, pituitrin is one of the greatest boons of the obstetrician. Every physician knows that no matter how smoothly a labor is progressing, his anxiety is not over until the placenta is expelled in its entirety and the uterus is contracting firmly. I make it a practice in every labor case, no matter how uneventful the progress, to have handy a syringe-full of an ampoule of pituitrin. After delivery, at the slightest sign of excessive hemorrhage I immediately inject the whole ampoule, whether the placenta has been delivered or not. If the placenta has not been delivered it will aid in its expulsion and by its action on the uterus check a tendency to further hemorrhage. If the placenta has already been expressed and hemorrhage follows, the pituitrin is immediately injected and then the other methods for the treatment of post-partum hemorrhage are proceeded with. When so used, it is rarely necessary, except in those cases where the pituitrin fails to act at all, to do more than to administer ergot by mouth and maintain the contractions of the uterus with the hand. The satisfaction derived from pituitrin when used for this purpose exclusively should render the profession thankful that it possesses this adjunct in the treatment of this terrible complication instead of trying to deflect the use of the drug into fields of known danger.

Medicolegal Notes.

Wrong Diagnosis Not Alone Actionable—Failure to Cure Does Not Raise Presumption of Negligence.—In an action against physicians for malpractice it was claimed that the defendants made a negligent and unskillful diagnosis of the plaintiff while he was suffering from osteomyelitis, and applied a vaccine treatment instead of operating. The case was one in which one of the defendants, consulted by the plaintiff, considered that he should have advice and assistance, and the other defendant was called into consultation. Together they took a history of the present ailment, and, learning of past ailments, they stripped the patient, that they might better observe the results of such past ailments and treatment. Numerous scars appeared from previous operations. Because of a history of osteomyelitis, they made use of the common tests to discover the presence of that disease, including pressure, blood count to determine whether there was an increase of white cells, microscopic examination of the blood for infection, test of blood pressure, urine analysis, and finally an x-ray examination of the affected arm, showing, as it appeared to them, that there was a normal condition of the bone. From all of this they determined that there was no osteomyelitis at that time and no need of a surgical operation and that a vaccine treatment was proper. There was a conflict between the physicians testifying hypothetically as to whether the symptoms indicated osteomyelitis at that time, and as to whether the proper method of treatment was followed, but the court did not go into that controversy, declaring that it must be governed by the principle well stated by Judge, now Chief Justice, Taft, in Ewing v. Goode (C. C.), 78 Fed., 442, as follows: "When a case concerns the highly specialized art of treating * * * with respect to which a layman can have no knowledge at all, the court and jury must be dependent on expert evidence. There can be no other guide, and, where want of skill or attention is not thus shown by expert evidence applied to the facts, there is no evidence of it proper to be submitted to the jury. Again, when the burden of proof is on the plaintiff to show that the injury was negligently caused by defendant, it is not enough to show the injury, together with the expert opinion that it might have occurred from negligence and many other causes."

The fact that the defendants were mistaken in their treatment was not alone sufficient to require them to respond in damages. A physician is not ordinarily liable for damages consequent upon an honest mistake or error in judgment in making a diagnosis, in prescribing a treatment, or in determining whether an operation is necessary, where there is a reasonable doubt as to the nature of the physical conditions involved, or as to what should be done in accordance with recognized authority and good current practice. A surgeon might possess great learning and skill, and, when performing a certain operation, might be as careful as possible, yet it might be that a prudent and skilful man of that profession, in the same circumstances and conditions, would not have performed such an operation; the difference being in their judgment as to the necessity of the operation. Gore v. Brockman, 138 Mo. App., 231; 119 S. W., 1082.

There is no presumption of negligence or of want of skill. The mistake of the physicians was in determining after careful diagnosis the method of treatment they would follow; that a cure would be effected by the use of vaccine, without surgery. Having determined the method of treatment, had there been a question as to whether they were careless and negligent or unskillful in the use of that method, there would clearly have been a question for the jury as to a fact; for instance, had they operated on the wrong arm (Sullivan v. McGraw, 118 Mich., 39; 76 N. W., 149), or sewed up a sponge in the abdomen (Gillette v. Tucker, 67 Ohio St., 106; 65 N. E., 865; 93 Am. St. Rep., 639), or rendered unskilful or negligent treatment after miscarriage (Becker v. Janinski, 15 N. Y. Supp., 675). Where, however, there is a state of fact conceded or proved, it becomes the duty of the court to draw the conclusion as a matter of law. Judgment for the plaintiff was reversed for a new trial.—Edwards v. Uland (Ind. App.), 131 N. E., 240.

Cross-Examination of Medical Witness as to Course of Bullet Through Clothing.—In a prosecution for homicide, objection was made to the introduction of the clothing of the deceased worn at the time he was shot. An issue was made as to whether deceased was facing the accused, when the bullet entered his body, or fleeing from him. The doctor who saw the body of the deceased was introduced by the accused, and testified that he thought the bullet entered the deceased's left breast. On cross-examination he was shown by the state the coat and vest worn by the deceased, and shown to be in the same condition as at the time of the homicide, and from his examination of same he testified that the fibre of the clothing appeared to be pushed in at the bullet holes in the back and pushed out at the bullet holes in front, and that from his examination of the clothing he would conclude that the deceased was shot in the back. This witness stated that he had been practicing medicine for over 20 years, and had had much experience in gunshot wounds. The Texas Court of Criminal Appeals holds that it was not error to ask him the questions shown on cross-examination, and that the same general experience which would qualify him to express his opinion as to the entry and exit of a bullet in the body would also qualify him to express his opinion as to the same matter with regard to the clothing, if, indeed, such testimony requires as a predicate that knowledge and experience which is ordinarily deemed necessary to an expert witness.—Eason v. State (Tex. Cr.) 232 S. W. 300.

Exhibition to Jury of Parts of Deceased's Body in Homicide Case.—The Montana Supreme Court holds that it is not error to admit in evidence the skull, or a portion thereof, of the deceased in a homicide case, where it is in effect a part of the testimony of a physician and is necessary to illustrate the character and extent of the injuries, and the injury caused to the head by the blow and that caused by shooting the deceased in the breast were inflicted at the same time and by the same parties. Parts of the body of the deceased may be exhibited to the jury in a homicide case, provided they are first identified and are shown to be in the same condition as when found after the homicide, or as at the time of burial.—State v. Byrne (Mont.) 199 Pac. 262.

MEDICAL RECORD.

THE SOLDIER IN ALL HIS RELATIONS.

THE first volume, or rather part of a volume,* of the medical and surgical history of the war, officially known as "The Medical Department of the United States Army in the World War," is just off the press of the Government Printing Office. In his letter of transmission to the Secretary of War, the Surgeon General states that the various parts of the history, "irrespective of sequence in volume numbers, will be published as the material becomes available. "Army Anthropology," therefore, however important, does not appear first because it is deemed the most important part of the history, but merely because it is the first to be ready for the printer. It contains 635 pages, including table of contents,, appendix, consisting of 139 statistical tables, and the index of 60 pages. It is bound in dark red buckram, with back imprint in gold. The text contains 194 statistical tables, and 42 plates, and gives practically everything one could desire to know about the physical relationships of a large number of the draft recruits who constituted our fighting forces in the recent war. The study which this part of the history represents, we are told in the introduction, involves the analysis of the three standard physical measurements of the Army, taken on 1,000,000 recruits; with special reference to physical defects, taken on 2,000,000 recruits; and of a set of 17 other measurements made of 100,000 troops at demobilization, for the purpose of securing dimensions for uniforms. The whole study gives an insight into the sizes and proportions of the American male population, ages 21 to 30 years, and of dimensions with reference to health and development, to geographical distribution and environment, and to race and color.

One who has had no experience along either anthropological or military lines might well ask the utility of such intimate details as are involved in this study, as did a civilian whose attention happened to fall upon the item, "blue eyes with brown spots." Discussing the importance of anthropology in the Army, the authors tell us that for over a century armies have prescribed limits of size for recruits on various grounds. It is urged, they say, that small men (under 60 inches) cannot carry the prescribed equipment. Men over 78 inches are more apt to suffer from circulatory and other diseases. The size of men has a relation to the standard food ration, which differs in the English and Italian armies because of the difference in body size of the soldiers. Troops in an Army camp containing a large proportion of South Italians and Polish Jews from New York City should use an average amount of food per man different from that of troops composed mostly of Scandinavians. The leg length is important for the classification of troops which are required to make long marches. A knowledge of proportions of facial features is essential to gas-mask manufacturers. A knowledge of the size and proportions of the body is essential to the proper cutting of uniforms; it will also aid in detecting pulmonary tuberculosis and cardiac disorders, as well as thyroid and other diseases. A knowledge of racial characteristics is often necessary to decide on classification when military organizations are being formed on racial lines, such as Negro regiments or Slavic legions. And finally, we are told, the whole system of identification, whether by finger prints or by Bertillon's proportions, belong to the field of anthropology.

Of the major physical characteristics and measurements—age, stature, weight, chest circumference, and build—stature is one of the most important from a medico-military point of view, as it is the basis by which may be judged the build or robustness of the man. Experience has shown that a certain chest circumference and a certain weight are essential for the successful soldier, but these measurements are to be judged not absolutely, but in relation to stature. The importance of stature in relation to weight and chest circumference depends on the fact that it gives a warning for tuberculosis, hook-worm, and other diseases. The varying relation of weight to stature is a measure of build, and build is of importance as an index of physical robustness and general health. Chest circumference is of medico-military importance, first, because it may be used to measure lung capacity, and second, because it is an index of certain diseases. It is used in obtaining the index of robustness, an index which is believed to give a fair measure of vital resistance. Important as are stature and weight for military and medico-military purposes, they are not so important as is the index of build, which tells something of the physical constitution of a man, and, by implication and as a result of experience, also something about his ability to withstand the stress of warfare. In the matter of robustness and military efficiency, the Army ideals of selecting men of medium stature, the authors hold, is justified. In connection with the draft of 1917, efforts were made on more than one occasion to raise the minimum stature (60 inches) to 63 inches. This was due to failure to recognize that there was in this country

*"Army Anthropology," Part One, Volume XV, "Statistics," Prefaced under the direction of M. W. Ireland, Surgeon General of the Army, by Charles B. Davenport, Carnegie Institution of Washington (formerly Major, S. C., U. S. A.), and Albert G. Love, Major, M. C., U. S. A.

a great number of short men belonging to the Mediterranean races and to the group of Polish Jews in whom the mean stature is only slightly above 63 inches. Experience in the Italian army indicated that even short men, if they are not too far removed from the standard of their race, are capable of performing excellent military service. The authors hold that if it ever again becomes necessary to institute a selective draft in this country it should not be forgotten that we have a great population of short men which includes many thousands for whom a stature of 60 inches is not a greater departure from the average than a stature of 65 inches is in men of the Nordic races.

Space does not permit the discussion of the many interesting questions involved in the various other dimensions — sitting height, span, sternal notch, height of pubic arch, neck circumference, breadth of shoulder, chest diameter, waist circumference, transverse diameter of pelvis, leg length, thigh circumference, calf circumference—the general comparative picture of white and negro troops; correlations of dimensions; eye color; hair color; and physical dimensions in relation to disease. The book is a "treasure trove" of information along all these lines, and since it is based on the largest number of such examinations ever recorded, it must prove of lasting interest and value from both anthropological and military points of view.

THE DIAGNOSIS OF CYSTS OF THE MESENTERY.

THE diagnosis of cysts of the mesentery at times offers such difficulty that it must remain problematical before the abdomen is opened. The size, consistency, fluctuation, and mobility may exist or be absent, so that no general rules can be laid down, and in spite of the great progress made in surgery of the abdomen there are still many cases in which the diagnosis of abdominal tumors is difficult, to say the least, so that exploratory laparotomy becomes practically necessary. However, a positive diagnosis of these cysts is based principally on the three following signs: (1) great mobility in every direction; (2) situation in the midline, and (3) a sonorous zone in front of the tumor. The latter sign has only a theoretical value, but mobility when very marked is certainly peculiarly characteristic of mesenteric cysts. This sign, however, soon vanishes in many cases on account of the development of adhesions to other viscera. When the growth is manifestly median, the presence of neoplasms of the spleen and kidneys can be eliminated, and if the cyst does not descend too far down bimanual palpation of the pelvic cavity will eliminate the diagnosis of ovarian cyst.

The tumor with which confusion is by far the most likely is a cyst of the ovary. At the onset of the process the lateral position of one and the median position of the other, and an attentive bimanual palpation of the pelvic cavity will leave no doubt as to the nature of the growth, but for this to be so the tumor must still be small. The mobility is very much greater in mesenteric cysts so long as they have not become adherent; they can then be moved in all directions while an ovarian cyst can be moved only up and down. Sometimes the percussion dullness is not uniform, as in ovarian cyst, some areas of tympany being present due to the interposition of coils of intestine between the cyst and abdominal parietes. The characters due to the location of the cyst become less distinct the lower the mesenteric tumor is placed, or when it dips into the pelvis and at the same time develops upwards in the mesentery. Occasionally, cysts of the broad ligament, instead of following their usual evolution, work up between the two folds of the mesentery and develop partially therein, and possibly cases of mesenteric cyst whose diagnosis is difficult may be secondary more often than is generally supposed. Hydronephrosis and cysts of the liver can hardly be mistaken for mesenteric cysts, but cysts of the omentum present the same symptomatology as those of the mesentery so that in each case an exploratory abdominal incision will be necessary to settle the diagnosis, and this likewise applies to cysts of the pancreas. A difficult diagnostic problem to solve is whether one is dealing with a fluid collection or a lipoma of the mesentery. Since both are situated between the two layers of the mesentery their objective signs are very similar. The consistency will not always be of much help, because many lipomata are almost fluctuating.

Secondary symptoms are common enough in cases of mesenteric cyst, consisting especially in abdominal distress, tension, and violent colic with the maximum pain around the umbilicus.

THE MODERN TREATMENT OF WOUNDS.

ALBRECHT sums up this subject from the postbellum angle in the *Wiener klinische Wochenschrift.* At the outbreak of the war the entire surgical profession were adherents of the doctrine of asepsis. It took but little time to convince them that something more than asepsis was to be demanded to control wound healing, since most wounds were already badly infected when they reached the surgeons. Hence it was necessary to introduce antiseptic methods. These had to be either physical or chemical. Physical methods varied widely comprising on the one hand the mechanical principles of excision, resection, drainage, and flushing, and at the other extreme the use of heat and light. Chemical methods comprised the use of germicidal substances, which at first proved highly disappointing inasmuch as they could not be made to penetrate the tissues. These substances, however, developed other desirable qualities in that they stimulated phagocytosis and lymphorrhea and thus indirectly assisted Nature to expel the deeply placed microorganisms. At the same time healing was also promoted. The author classes wounds, for practical purposes, into recent, infected, and granulating. To

be recent a wound must have been inflicted within six or eight hours. Such lesions must be thoroughly cleansed and trimmed of all damaged fringe.

The only antiseptic used should be iodine tincture, on all doubtful surfaces. Primary complete suture, is then practised as an ideal which, however, does not usually make good in practice. The author would make the standard treatment one of incomplete suture and gauze drainage. Surgeons differ notably concerning the treatment of infected wounds. All agree as to a proper rest position. Wet dressings have more partisans than dry ones. Gauze dressings appear to exert a suction on the wound surfaces. If the discharges cannot readily be taken up by gauze, irrigation should be substituted.

Baths at blood heat are not sufficiently valued. In progressive infection the author recommends the permanent bath. When other treatment indicated has been carried out so that complications are for the time discounted the best resource is air, including the use of hot air. This has drawbacks in the shape of desiccation and cooling off, neither of which is desired. The main object of air treatment is the stimulation of wound secretions which it tends to bring about like wet dressings, but in quite a different fashion. Solar light is of use and is readily combined with hot air, as may also be the quartz lamp. Of chemical applications to infected wounds four classes were found of value during the war, namely, derivative of iodine, chlorine, quinine, and aniline. Of the first named isoform and Pregel's solution may be mentioned while the best known chlorine derivative was realized in the Carrel-Dakin solution. Of the quinine derivatives vuzin was the best known, and of the anilines pyoctanin and trypaflavin. This class of chemical antiseptics causes a flow of lymph over the surface of the wound. The granulating wound is best treated with ointments. To sum up in a formula, the ideal treatment of wounds is, however secured, an autoantisepsis. As a rule all other methods act by stimulating Nature's defenses—something which asepsis cannot do.

Animal Reservoirs of Virus.

Bacteriological infections might perhaps die out were there no such creatures as reservoir animals to harbor them in the latent intervals of diffusion of the diseases. At one time such a reservoir was looked on as more or less exceptional, but the fact is becoming realized that the greater number—and for all we know all—of bacteriological diseases have their special shelter of this kind. It need not follow in all cases that the reservoir helps to spread the disease. There is a possibility today that the rabbit can harbor the treponema but it can hardly aid in the dissemination of the disease syphilis. The rabbit spirochete may never have been in the human body at all. Dr. Joyeux, an authority on exotic and parasitic diseases, points out in *La Presse Médicale* for November 9, 1921, xxix, 90, that the sand-fly has a reservoir in the gecko lizard, and, by the same token, man is a reservoir for the reptile. Proof that the sandfly can carry the germ (*Leishmania*) of oriental boil from the lizard to man has not yet been completely supplied. The armadillo has long been known as a reservoir of a trypanosome which causes Chagas's disease. Several biting insects are known to be the medium of transmitting the disease from armadillo to man. The latter animal is probably not the exclusive reservoir, for the cat and also a species of wild guinea pig are more than suspected. The author omits mention of the crocodile as the reservoir of the trypanosome of sleeping sickness. Rats, or rather several of the rodent tribe, are reservoirs *par excellence*, for they harbor the causes of bubonic plague, rat-bite disease, and Rocky Mountain fever, the tick in question having as a host a small rodent, the *Citellus colubianus*. The goat is the reservoir for Malta fever and the dog may harbor the cause of kala-azar.

The Cancerogenic Substance of Tar Cancer.

The cancerogenic property of certain substances like tar, paraffin, soot, etc., is not the simple proposition which at first sight it appears to be. It is not enough to speak of "irritation" as if that word implied finality. Recently it has been shown that tarry principles may contain arsenical impurities. It must be shown exactly what the exciter of cancer cell formation is chemically. In the *Schweizerische medizinische Wochenschrift* for November 10,1921, li, 45, Bloch and Dreyfuss give an account of experimental mouse cancer of the skin with lymph-node and pulmonary metastases in which the nominal exciter was tar. The next step was to isolate from the complex substance known as crude tar the specific cancerogenic substance. From crude tar the authors passed to special purified fractions and found in part the same positive results. The chemical control of this research is necessarily long and tedious but so far as the work has gone many of the tarry ingredients have been eliminated. Extraction by boiling benzol and distillation may be used to eliminate many of the bases and phenols. The substance still unextracted which does not distill off is highly cancerogenic and thus far has not failed to engender the disease in the space of 4 months or less in a highly malignant form. Phenols and bases of low boiling point, such as have been extracted from the crude tar, are, interesting to relate, able to cause the formation of benign tumors in the same mice. It would be interesting to know whether these substances would have a similar effect in man, for of course it is very unsafe to argue from a cancerophilic mouse to men, the majority of whom are not constitutionally predisposed to malignant neoplasms.

The Medical Record Service Bureau.

Almost daily the Medical Record receives inquiries, from subscribers and others, on questions relating to medicine in all its branches—bacteriology, laboratory tests, new methods of treatment, medical practice laws in various States and foreign countries, bibliography, and every conceivable topic. These questions have grown to be so numerous that

the task of answering them has become too great for the office editorial staff. It has therefore been decided to secure the services of a special staff to whom these questions may be referred, and all our subscribers are invited to make use of this service freely. The questions should be typewritten, if possible, on one side of the sheet only, and the name and address of the querent should be on the same sheet. The answers will be returned by mail as promptly as possible, but when the questions are of general interest they may be published, with replies, in our columns. The name of the correspondent will not be given, however, without his consent.

News of the Week.

Mortality From Organic Diseases of the Heart.—The Department of Commerce, through the Bureau of Census, has just published figures showing that 124,000 deaths were due to organic diseases of the heart in the death registration area of the United States in 1920, and if the rest of the United States had as many deaths from this cause in proportion to the population, the total number of deaths from organic diseases of the heart in the entire United States for 1920 was 151,000, while for 1919 the number is estimated as 138,000, or 13,000 less than for 1920. For 1920 the rate was 141.9 against 131 per 100,000 population for 1919. "Adjusted" rates based on the standard million population have been calculated to permit better interstate comparisons for the year 1920. The highest adjusted rate from organic diseases of the heart for 1920 is 180.8 per 100,000 for the State of New York and the lowest is 87.3 for Kentucky. For States in which at least 10 per cent of the population was colored, adjusted rates have been calculated separately for the white and colored populations. In this group of States the highest adjusted rate for the white population is 179.8 per 100,000 for New York, and the highest rate for the colored population is 248.3 per 100,000 for the same State, while the lowest adjusted rate for the white population is 75 for Mississippi and the lowest for the colored population is 112 for Florida.

New York and Chicago Death Rates for 1921.—The death rate for New York City during 1921 was the lowest ever recorded in this city according to the mortality statistics made public by the Health Department. The general death rate in 1921 was 11.17 per 1,000 of the population, as compared with 12.93, which was considered a phenomenally low record in 1920. This means a saving of 8,992 lives. Ten years ago the death rate was 16 per 1,000. The infant death rate for 1920 was 71.1 per 1,000, the lowest rate ever reached by a great city. The 1920 rate was 85 per 1,000 living births. The death rate of children under five years of age in 1920 was 30.8, while in 1921 it was 23.8. Chicago has gone New York one better, with a mortality rate slightly under 11 per 1,000 of the population. This means a saving of 4,000 above that of 1920. Health Commissioner Dr. John Dill Robertson believes Chicago holds the record as the healthiest of any of the big cities of the country.

Campaign to Improve Health Conditions in the Philippines.—Governor General Wood has started an intensive campaign to improve health conditions in the Philippine Islands by teaching the people how to avoid and combat the most common diseases. He has instructed the Director of the Philippine Health Service to prepare a circular setting forth the causes of various diseases and the methods which can be used to prevent them and stamp them out. The circulars are to be posted in public places in every municipality of the islands, and are to be read to every class in the public schools throughout the archipelago.

Railroads Reduce Deaths.—An analysis of the latest Interstate Commerce Commission figures on the annual accident records of all railroad in the United States shows that fewer persons were killed in 1920 than in any year since 1898. The analysis, prepared by a committee of the American Railway Association, gives credit for this achievement to the combined efforts of the officers and employees of the railroads, the public, and the press in systematic safety education. In 1919 the ratio of passengers carried safely to passengers fatally injured was 4,529,000 to and in 1920 was 5,673,000 to 1.

The Physical Examination of the Employees of the New York City Health Department.—The New York City Health Department, which was one of the pioneers in instituting periodical physical examinations of its employees, having made provision for this work in 1914, in its Monthly Bulletin for November, 1921, submits the results of these examinations for the year 1920. The records show that a total of 8,512 examinations were made in 1920, of which 2,297 were men and 6,215 were women. These reports now extend over a period of six years. The one noticeable feature in the first reports is a rather larger number of cardiac impairments found in the male than in the female employees, for in every succeeding report the number of cardiac impairments is almost uniformly greater among women than among men. With regard to high blood pressure, the usual order of things is reversed, for the women in the department present persistently higher blood pressures than the men, showing that such impairments depend as much upon occupation as upon sex. The department has a large number of women engaged in hospital and field work which is vastly more laborious than the office work which engages so many male employees. Among women is found more anemia, low weight and low blood pressure than among men, as well as more indigestion and constipation. Thyroid enlargement, visceroptosis, and varicose veins are also more frequent among women than among men. The statistics show with what relative infrequency clerical workers, even those with a poor family history, show hypertension; it is the hard workers, those who toil day after day and who, perhaps, are subjected to nervous or mental tension at the same time, who so quickly show the signs of wear and tear, especially if the inherited arterial "rubber" is not of the best quality. The report calls attention to the importance of these periodical physical examinations in that they afford excellent opportunities for educational work on pre-

ventive medicine, for while didactic lectures and health leaflets are very useful, nothing can take the place of the individual instruction adapted to the patient's special needs. They also show in this group, as in similar groups, that a surprisingly large number of people who think they are well have ailments which they have never suspected.

The de Roaldes Prize of the American Laryngological Association, a gold medal of the value of $150, offered for the best original thesis upon a subject pertaining to Laryngology or Rhinology, is now open for competition to non-members of the association. Theses must be in the hands of the chairman of the prize committee, Dr. D. Bryson Delavan, 40 East Forty-first Street, New York, prior to April 1, 1922.

Yale School of Medicine to Have New Buildings.—Announcement has been made that the Yale Corporation and the Sterling trustees have decided to appropriate $1,320,000 from the Sterling funds for the erection of a new building for the Yale School of Medicine, to be known as the Sterling Hall of Medicine. The structure is to be built on property recently acquired by the university and will contain a library of 12,000 volumes, an auditorium, offices, rooms for unmarried instructors and laboratories, with an animal house and a power house adjoining. The project will carry out plans in the university's reorganization program for expansion of the School of Medicine.

New Medical Building at University of Alabama.—The contract has been let for a new medical building to be erected at a cost of $82,500 at the University of Alabama. Work will be commenced at once.

Law Suggested to Compel Fireproof Hospitals.—The Wisconsin State Industrial Commission has under consideration the advisability of amending the State building code to require all hospitals hereafter constructed to be of strictly fireproof material. This is brought out in a circular letter which the commission is sending to all physicians and surgeons in Wisconsin in which it asks for an expression of opinion as to the advisability of the change.

Seneca Falls Typhoid Suits to Start Soon.—The first of a series of suits against the Gould Manufacturing Company and the Seneca Water Company, growing out of the recent typhoid epidemic at Seneca Falls is scheduled for January 16 in the Supreme Court at Rochester, N. Y.

Leprosy in New York.—During a lecture delivered by Dr. William L. Somerset, Chief Diagnostician of the New York City Health Department, to physicians in the department building several lepers having the disease in "non-contagious" form were exhibited. It was stated that leprosy was much more prevalent in the community than was generally known, there being between eighty and ninety known cases of leprosy in New York City. These patients are kept under close observation by the Health Department. It was explained that they constituted no menace so long as they had no open lesions.

Physicians' Building for New Rochelle.—Through cooperative effort the erection of a large office building centrally located in New Rochelle, N. Y., and intended exclusively for the use of medical and surgical practitioners, has been commenced. Formal exercises were held on December 31, when the cornerstone was laid. Dr. George David Stewart of New York delivered the address of the day. While it is not intended that the project shall result in a close corporation, opportunity will be afforded for the development of the "group idea" in the practice of medicine. The new building will cost about $300,000.

New York State Scores High Record for Insanity.—The report of the State Charities Aid Association recently submitted to the State Hospital Commission states that more persons were sent to hospitals for the insane last year than in any previous year. At the end of 1921 patients in the thirteen State hospitals for the insane numbered 39,736, an increase of 1,445 over the number there a year ago and 6,642 more than the rated capacity of the hospitals. The report shows that those who had gone insane as the result of the use of alcohol were fewer than normal and that the increase was due partly to economic conditions and partly to war casualties. The report urges the establishment of occupational schools in connection with the hospitals as a therapeutic measure which will hasten the recovery of certain classes of patients, and also that mental clinics be more thoroughly organized and widely extended.

Hospital Notes.—A new and modern hospital and training school for nurses is to be opened in Cartagena, Colombia. Four Philadelphia doctors sailed on the steamship Santa Marta on December 21 to take charge of the new institution. They are: Dr. Raoul Bernett y Cordova, a resident physician of Pennsylvania Hospital; Dr. Kempton P. A. Taylor of Chestnut Hill; Dr. W. E. Sickner, Ph.D., of Minnesota, and Dr. Rafael Calvo, dean of the medical school of the University of Cartagena.

A supervisor's committee appointed to investigate regarding a suitable memorial for the soldiers of Madison County, N. Y., have recommended the erection of a county tuberculosis hospital. The site, buildings, and plant are to be provided through public subscription and the institution is to be maintained at county expense.

Plans have been announced for the development of St. Agnes Hospital, Fond du Lac, Wis., at an outlay of $500,000. The plans provide for an additional service unit of 100 beds, and for separate medical, surgical, maternity, and children's units.

A modern five-story hospital to cost approximately $150,000, is to be erected at Logan, W. Va., by an association of Huntington and Logan physicians. Construction work will be begun as soon as weather conditions permit.

Contracts have been let for a $75,000 State tuberculosis sanatorium at Norton, Kan., and active construction work is to be begun in the near future.

Lyon County will open its new $300,000 hospital near Emporia, Kan., on February 1.

Dr. Charles A. Powers of Denver, Colo., has been decorated by the President of France with the Legion of Honor (Chevalier) and with the Medaille de la Reconnaissance Française (bronze)

for services rendered the French wounded during the World War.

Dr. Glen E. Cullen has been elected associate professor of research medicine at the University of Pennsylvania.

Dr. George J. Heuer, associated professor of surgery at Johns Hopkins University, has accepted the chair of professor of surgery at the University of Cincinnati and assumed the duties of his new office on January 1. Dr. Mont R. Reid, formerly resident surgeon of Johns Hopkins Hospital, will accompany Dr. Heuer.

Dr. Leo J. Palmer of Watertown, N. Y., has been elected county physician of Jefferson County.

Dr. James B. Nicholls has been elected medical director of the Catawba State Tuberculosis Sanatorium by the Virginia State Board of Health.

Dr. Foster Murray, until recently first assistant resident physician at the Trudeau Sanatorium at Saranac Lake, N. Y., has been placed in charge of the four clinics conducted by the Tuberculosis Committee in the Borough of Brooklyn, N. Y.

Dr. Harry C. Clifton has resigned the position of city physician of Hartford, Conn.

Dr. Frederick S. Crossfield has been reelected rhinologist and laryngologist of the Hartford Hospital, Hartford, Conn.

Dr. Guilford H. Sumner has resigned his position of secretary of the Iowa State Board of Health, which he has held for the past twelve years.

Mr. Curtis E. Lakeman has been appointed secretary of the New York State Department of Health to succeed Dr. John A. Smith, resigned.

Dr. Reginald Farrar, representative of the Epidemics Commission of the League of Nations, died a victim of typhus fever in Moscow on December 28.

Comparative Birth Rates Among the White and Colored People in the United States.—The Department of Commerce, through the Bureau of the Census, announces that within the birth registration area of the United States, 1,395,523 births were reported among the white population and 103,796 among the colored in 1920, and that the birth rate per 1,000 females was 48.2 for the white and 52.8 for the negro. The area to which these figures relate includes 23 States and the District of Columbia and comprises 62.3 per cent of the total white population and 37.2 per cent of the total negro. In the case of the white population the births were further classified by country of birth of mother, the rate being then based upon the female population born in the same country. The lowest rate (38.2) for the white population appears for women born in England, Scotland and Wales, while in striking contrast are the rate for women born in Italy (160), and for the Japanese (188.5). For the negroes the highest rate (61.5) is for North Carolina and the lowest (10.1) for Maine, in which State only six negro births were recorded. That northern States do not always have low birth rates among the negro population is shown by the rate (54.7) for Massachusetts and the rate (46.5) for New York State. The rate for Indians was 48.3, though the range of rates for this part of our population was remarkably wide, from 16.7 in Maine to 114.7 in Virginia. It may be of interest to note that the 1,968 births of Indians exceeded the number of deaths of Indians in the same registration area by 90, indicating that the Indian population did not decrease in the birth registration area in 1920.

Medical Society Elections.—The Lehigh County (Penn.) Medical Society, at its regular monthly meeting held in Allentown, Dec. 13, 1921, elected the following officers for the ensuing year: *President,* Dr. I. D. Weida; *Vice-Presidents,* Dr. J. D. Matz and Dr. M. S. Kleckner; *Secretary,* Dr. J. T. Butze; *Treasurer,* Dr. W. D. Kline.

The Dallas County Medical Society, at its meeting in Selma, Tex., Dec. 9, 1921, elected the following officers for the ensuing year: *President,* Dr. F. W. Burns; *Vice-President,* Dr. C. D. Feulner; *Secretary-Treasurer,* Dr. P. Y. Donald; *Health Officer for Dallas County,* Dr. B. T. Lee.

The Taylor County Medical Society, at its regular meeting held in Abilene, Tex., Dec. 13, 1921, elected the following officers for the ensuing year: *President,* Dr. J. M. Estes; *Vice-President,* Dr. J. L. Pickard; *Secretary-Treasurer,* Dr. Stewart Cooper.

The Montgomery County Medical Society, at its regular meeting held in Montgomery, Mo., Dec. 17, elected the following officers for the ensuing year: *President,* Dr. David Nowlin; *Vice-President,* Dr. G. E. Muns; *Secretary,* Dr. Buell Menefee.

The Seaboard Medical Society, at its twenty-sixth annual meeting held in Norfolk, Va., Dec. 8, 1921, elected the following officers for the ensuing year: *President,* Dr. Joseph L. Sproull, Sanitarium, N. C.; *First Vice-President,* Dr. Joseph T. Buxton, Newport News; *Second Vice-President,* Dr. W. E. Warren, Williamston, N. C.; *Third Vice-President,* Dr. Cora Z. Corpening, Suffolk; *Fourth Vice-President,* Dr. F. T. Gates, Manteo, N. C.; *Treasurer,* Dr. George A. Caton, New Bern, N. C. (re-elected); *Secretary,* Dr. Clarence Porter Jones, Newport News (re-elected).

The Southern Surgical Association, at its thirty-fourth annual meeting held in Pinehurst, N. C., Dec. 13-15, 1921, elected the following officers for the ensuing year: *President,* Dr. C. Jeff Walker, New Orleans; *Vice-Presidents,* Dr. Vilray P. Blair, St. Louis; Dr. Robert L. Gibbon, Charlotte; Dr. Hubert A. Royster, Raleigh; *Secretary-Treasurer,* Dr. Guy L. Hunner, Baltimore.

The Sixth District Branch of the Georgia Medical Association, at its annual meeting held in Macon, Dec. 14, 1921, elected the following officers for the ensuing year: *President,* Dr. A. G. Alexander, Forsyth; *Vice-President,* Dr. H. W. Copeland, Jackson; *Secretary,* Dr. G. Y. Massenburg, Macon.

The Onondaga Medical Society, at its meeting held in Syracuse, N. Y., Dec. 14, 1921, elected the following officers for the ensuing year: *President,* Dr. George W. Hawley; *Vice-President,* Dr. H. G. Weiskotten; *Secretary,* Dr. Philip Cooper; *Treasurer,* Dr. George M. Retan.

The Fulton County (Ga.) Medical Society, at its annual meeting held in Atlanta, Dec. 16, the following officers were elected for the ensuing year: *President,* Dr. Rufus T. Dorsey; *Vice-President,* Dr. H. R. Donaldson; *Secretary-Treasurer,* Dr. Grady Clay; *Censor,* Dr. W. E. Pearson.

THE MARSHALL COUNTY MEDICAL ASSOCIATION at its regular meeting held in McMechen, W. Va., Dec. 13, 1921, elected the following officers for the ensuing year: *President*, Dr. P. D. Barlow, Wheeling; *Vice-President*, R. A. Ashworth, Moundsville; *Secretary*, Dr. Conklin, Wheeling.

THE SEDGWICK COUNTY MEDICAL ASSOCIATION, at its annual meeting held in Wichita, Kans., Dec. 13, 1921, elected the following officers for the ensuing year: *President*, Dr. W. P. Callahan; *Vice-President*, Dr. John W. Cheney; *Secretary*, Dr. Leon Matassarin; *Treasurer*, Dr. A. E. Gardner; *Censor*, Dr. L. T. Warren.

THE AVOYELLES PARISH MEDICAL SOCIETY, at its regular meeting held in Cottonport, La., Dec. 14, elected the following officers for the ensuing year: *President*, Dr. Philip Jeansonne, Plaucheville; *Vice-President*, Dr. Kirby A. Roy, Mansura; *Secretary-Treasurer*, Dr. S. J. Couvillon.

THE BUCHANAN COUNTY MEDICAL SOCIETY, at its annual meeting held in St. Joseph, Mo., Dec. 7, 1921, elected the following officers for the ensuing year: *President*, Dr. Fred H. Ladd; *First Vice-President*, Dr. E. S. Ballard; Second Vice-President, Dr. W. H. Minton; *Secretary-Treasurer* (re-elected), Dr. O. C. Gebhart.

THE PARKER-PALO PINTO COUNTY MEDICAL ASSOCIATION, at its annual meeting held in Weatherford, Tex., Dec. 14, elected the following officers for the ensuing year: *President*, Dr. Charles MacNelly; *Secretary-Treasurer*, Dr. P. R. Simmons.

THE COLUMBUS (OHIO) ACADEMY OF MEDICINE, at its regular meeting held December 16, 1921, elected the following officers for the ensuing year: *President*, Dr. E. A. Hamilton; *Vice-President*, Dr. W. C. Murphy; *Secretary*, Dr. James A. Beer; *Trustee*, Dr. E. W. Schueller.

THE KENT COUNTY (MICH.) MEDICAL SOCIETY, at its annual meeting held in Grand Rapids, Dec. 14, 1921, elected the following officers for the ensuing year: *President*, Dr. Alden H. Williams, Grand Rapids; *Vice-President*, Dr. W. E. Strong, Rockford; *Secretary-Treasurer*, Frank Cameron Kinsey.

THE WAYNE COUNTY (N. Y.) MEDICAL SOCIETY, at its annual meeting held in Lyons, Dec. 14, 1921, elected the following officers for the ensuing year: *President*, Dr. J. R. Sanford, Newark; *Vice-President*, Dr. Robert S. Carr, Williamson; *Secretary and Treasurer*, Dr. L. H. Smith, Palmyra.

THE MEDICAL SOCIETY OF CHAUTAUQUA COUNTY (N. Y.), at its annual meeting held Dec. 14, 1921, elected the following officers for the ensuing year: *President*, Dr. George E. Smith, Dunkirk; *First Vice-President*, Dr. J. W. Morris, Jamestown; *Second Vice-President*, Dr. M. S. Coxe, Dunkirk; *Secretary*, Dr. W. J. Sullivan, Dunkirk; *Treasurer*, Dr. Lester D. Bowman, Jamestown; *Censors*, Dr. A. Wilson Dods and Dr. N. G. Richmond, Fredonia.

THE ACADEMY OF MEDICINE OF CLEVELAND, OHIO, at its annual meeting held Dec. 16, 1921, elected the following officers for the ensuing year: *President-Elect* for 1923, Dr. Clyde L. Cummer; *Vice-Presidents*, Dr. C. W. Stone; *Trustees*, Dr. George F. Thomas and Dr. S. J. Webster; *Executive Secretary*, Guy M. Wells.

THE SETON HOSPITAL, CINCINNATI, at its meeting held Dec. 8, 1921, elected the following staff officers: *President*, Dr. Carroll DeCourcy; *Vice-President*, Dr. Edward Kennedy; *Secretary-Treasurer*, Dr. Joseph DeCourcy.

THE PENNSYLVANIA HOSPITALS ASSOCIATION, at its annual meeting held in Harrisburg, Dec. 7, 1921, elected the following officers for the ensuing year: *President*, Dr. Daniel D. Test, Philadelphia; *First Vice-President*, Dr. J. C. Biddle, Ashland; *Second Vice-President*, Col. J. H. Rigger, Pittsburgh; *Treasurer*, Dr. Elmer E. Matthews, Altoona.

THE NATIONAL SOCIETY FOR THE PROMOTION OF OCCUPATIONAL THERAPY, at its fifth annual meeting held in Baltimore, Md., Oct. 20-22, 1921, elected the following officers for the ensuing year: *President*, Dr. H. J. Hall; *Vice-President*, Dr. G. Canby Robinson; *Secretary-Treasurer*, Mrs. Eleanor Clark Slagle; *Chairman of Committees: Finance*, Miss Marion R. Taber; *Publicity and Publication*, Dr. W. R. Dunton, Jr.; *Research and Efficiency*, Mrs. T. B. Kidner; *Installations and Advice*, Mrs. E. C. Slagle; *Teaching Methods*, Miss Ruth Wigglesworth; *Members of the Board of Managers*, Mrs. Carl Henry Davis and Mrs. C. J. Sullivan.

THE MEDICAL SOCIETY OF THE DISTRICT OF COLUMBIA, at its recent annual meeting held in Washington, D. C., elected the following officers for the ensuing year: *President*, Dr. A. W. Boswell; *First Vice-President*, Dr. William H. Hough; *Second Vice-President*, Dr. Prentiss Willson; *Corresponding Secretary*, Dr. J. Russell Verbrycke; *Recording Secretary*, Dr. Coursen B. Conklin; *Treasurer*, Dr. E. G. Seibert.

THE SEABOARD MEDICAL SOCIETY, at its meeting in Norfolk, Va., Dec. 8, 1921, elected the following officers for the ensuing year: *President*, Dr. Joseph L. Spruill, Sanatorium, N. C.; *First Vice-President*, Dr. Joseph T. Bruxton, Newport News; *Second Vice-President*, Dr. W. E. Warren, Williamston, N. C.; *Third Vice-President*, Dr. Cora Z. Corpening, Suffolk; *Fourth Vice-President*, Dr. F. T. Gates, Manteo, N. C.; *Treasurer*, Dr. George A. Caton, Newbern, N. C. (re-elected); *Secretary*, Dr. Clarence Porter Jones, Newport News (re-elected).

THE NEW YORK STATE SOCIETY OF INDUSTRIAL MEDICINE, at its first annual meeting held in Syracuse, Dec. 7, elected the following officers for the ensuing year: *President*, Dr. T. G. Smith, Schenectady; *First Vice-President*, Dr. C. H. Weston, New York City; *Second Vice-President*, Dr. R. W. Chaffee, Syracuse; *Secretary*, Dr. Myer Bloom, Binghamton; *Treasurer*, Dr. S. M. Slater, Rochester.

THE COVINGTON COUNTY (ALA.) MEDICAL SOCIETY, at its meeting held in Mobile, Dec. 6, 1921, elected the following officers for the ensuing year: *President*, Dr. F. Young, Florala; *Vice-President*, Dr. B. C. Stewart, Opp; *Secretary-Treasurer*, Dr. L. E. Broughton, Andalusia.

THE WALKER COUNTY (ALA.) MEDICAL SOCIETY, at its regular meeting in Jasper, Dec. 10, 1921, elected the following officers for the ensuing year: *President*, Dr. J. A. Goodwin, Jasper; *Vice-President*, Dr. G. S. Gilder, Carbon Hill; *Secretary*, Dr. J. F. Alexander, Jasper; *Censor*, Dr. W. M. Cunningham, Corona; *County Physician*, Dr. A. M. Stovall, Jasper.

THE SOMERVILLE (MASS.) MEDICAL SOCIETY, at its annual meeting held Dec. 8, 1921, elected the following officers for the ensuing year: *President*,

Dr. W. D. Ruston; *Vice-President*, Dr. Eugene L. Maguire; *Secretary-Treasurer*, Dr. E. H. Robbins.

The Hillsborough County (Fla.) Medical Society, at its annual meeting held in Tampa, Dec. 6, 1921, elected the following officers for the ensuing year: *President*, Dr. L. J. Efird; *Vice-President*, Dr. S. F. Adamo; *Secretary*, Dr. C. R. Marney; *Treasurer*, Dr. J. C. Chandler; *Censor*, Dr. E. F. Carter.

The Rutherford County Medical Association, at its annual meeting held in Murfreesboro, Tenn., Dec. 8, elected the following officers for the ensuing year: *President*, Dr. A. N. Gordon; *Vice-President*, Dr. J. C. Overall; *Secretary-Treasurer*, Dr. J. A. Scott.

The Douglas County Medical Society, at its annual meeting held in Superior, Wis., Dec. 7, 1921, elected the following officers for the ensuing year: *President*, Dr. T. H. Shastid; *Vice-President*, Dr. H. L. Sarvela; *Secretary-Treasurer*, Dr. F. J. Broghammer.

Obituary Notes.—Dr. Howard B. Cross of the Rockefeller Institute of Medical Research, New York, who sailed for Vera Cruz on Nov. 23, 1921, to take charge of the institute's laboratories in that city, established to carry on the fight against yellow fever, succumbed to the disease on Dec. 27, at the age of thirty-two years. He was graduated from Oklahoma University School of Medicine, and was a graduate student of Chicago and Johns Hopkins Universities. In June, 1921, he was awarded the degree of doctor of philosophy by Johns Hopkins University. In making the announcement of Dr. Cross' death Dr. Simon Flexner said: "Dr. Cross gave his life willingly in order that one of the great plagues of humanity might be overcome and destroyed. By his death the science of bacteriology has lost an able, conscientious and devoted worker and the world a brave and generous spirit."

Dr. A. Warren Penniman died of angina pectoris at his home in Berkeley, Cal., on Dec. 15, at the age of sixty-two years. He was graduated from the University of Vermont College of Medicine in 1889.

Dr. Richard B. Cumming of Wayne, Mich., a graduate of New York University Medical College in 1885, died on Dec. 20, at the age of sixty-three years.

Dr. Alexander Drill of Princeton, Wis., a graduate of the Marquette School of Medicine in 1916, was instantly killed in an automobile accident in Milwaukee, Wis., on Dec. 11. Dr. Drill, who served in the Medical Corps of the Army during the World War, was twenty-six years of age.

Dr. John S. Evans of Brookfield, Mo., a graduate of the Missouri Medical College, St. Louis, in 1890, died on Dec. 21, at the age of fifty-six years.

Dr. Albert Van Sickle of Brooklyn, N. Y., died of heart disease at his home on Dec. 27, at the age of forty-nine years. He was graduated from the College of Physicians and Surgeons, Columbia University, in 1896.

Dr. Samuel Rutherford Oliphant of New York City and Mount Vernon, N. Y., died in New Orleans, La., on Dec. 26. He was formerly a member of the Mount Vernon Board of Health and of staffs of the Mount Vernon, Demilt and Post-Graduate Hospitals.

Dr. T. J. Whitney, a retired physician of Jamestown, N. Y., who had practised medicine for over fifty years, died on Dec. 24, at the age of seventy-nine years.

Dr. Robert Childs Patterson was shot and instantly killed in his office in Saranac Lake, N. Y., on December 244, by a mentally deranged ex-service man. He was graduated from McGill University Faculty of Medicine, Montreal, Can., in 1902. He was a fellow of the American Medical Association and a member of the American Climatological and Clinical Association, the American Pathological and Bacteriological Society, and the National Tuberculosis Association. Dr. Patterson had been connected with the tuberculosis work at Saranac for twelve years. He was forty-three years of age.

Dr. Harry S. Martin of Spokane, Wash., a graduate of the Victoria University Medical Department in 1884, died on December 11, at the age of sixty-seven years.

Obituary.

WESLEY GROVE VINCENT, M. D., F. A. C. S.

NEW YORK.

Dr. Wesley Grove Vincent of this city died suddenly on Tuesday evening while performing a minor operation in his office. The cause of his death was heart disease, a malady which has killed several prominent physicians of this city in the past year. He was born in Oak Bluffs, Mass., in 1871, and received his arts degree from Yale University in 1896 and his medical degree from the same institution in 1900. He was assistant surgeon to the New York Post-Graduate Hospital and professor of surgery in the Post-Graduate Medical School, and was a member of the Post-Graduate Alumni Association, the New York Academy of Medicine, the New York County and State Medical Societies, and the American Medical Association.

Dr. Vincent was a man of superior education, cultured, an agreeable companion, a faithful friend, and a surgeon of excellent judgment and fine technique. For many years he had been a valued member of the editorial staff of this journal. His death will be deeply felt as a personal loss by all his associates.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

London, December 17, 1921.

The Causation of Rickets.—The question of the causation of rickets is by no means settled. In fact, in this country there is as much confusion concerning its etiology as there ever was. Perhaps the majority of investigators do not now recognize rickets as a deficiency disease in the same category as beri-beri and scurvy and, perhaps, pellagra. Some there are who even deny that diet plays any particular part in bringing about this condition, certainly, they say, not the predominant part. Prof. Noel Paton and Dr. Leonard Findlay of Glasgow and Dr. Dick of London are the most thoroughgoing exponents of the theory

that rickets is caused, if not entirely, at least mainly by bad environment, lack of fresh air and exercise, and by living under insanitary and unhygienic conditions. Prof. Noel Paton and Mr. A. Watson a few months ago conducted a series of experiments with puppies to test the validity of their views and from the results obtained concluded that diet played but a very subordinate rôle in producing lime starvation, and that, therefore, the conclusions arrived at by those responsible for a report on the subject issued by the Medical Research Council to the effect that rickets was essentially a dietetic disease, chiefly due to the lack of the fat soluble vitamine A were incorrect. Since then, indeed only a few weeks ago, another report got up by Prof. Mellanby has been published by the Medical Research Council, in which some of the statements made in the former report are considerably modified. Much less stress is now laid upon the fat soluble vitamine A as the principal cause of rickets, although the vitamine is still regarded as the most important factor. However, despite the views of the school headed by Noel Paton, most authorities continue to consider rickets a dietetic disease, but not in the narrow sense conceived by those who hold that the fat soluble vitamine A occupies a similar position to that of the anti-scorbutic vitamine in causing scurvy. Hess and Unger, as the result of their investigations, than which no more thorough were ever carried out, stated that rickets was assuredly a dietetic disease, although the fat soluble vitamine A did not deserve the prominent position attributed to it by many observers. Harriette Chick and colleagues, working in Vienna, affirmed that they were firmly of the opinion that it was a dietetic disease, the result of malnutrition, because in Vienna the hygienic conditions were satisfactory, or at any rate they would not explain the physical deterioration among children which was evident on all sides. It was a hunger disease which might exhibit itself in its most advanced stages as osteomalacia. Of all the opinions so freely expressed of late, with regard to the causation of rickets, none appeals to common sense and reason with greater force than those set forth by Dr. Eric Pritchard. His picturesque suggestion, if such an adjective is applicable when referring to a disease of rickets, is briefly that in rickets, calcium, "available base," is withheld from its normal function of developing bone, because it becomes more urgently required to neutralize acid products of incomplete oxidation. The cheaper bases are so much called upon that they become depleted and then the more expensive bases, as calcium and iron, are pressed into service. The withdrawal of a considerable amount from bone formation results in an insufficiency of lime in the bone and, consequently, rickets. Although the hydrogen-ion concentration of the blood has been shown to be normal in rickets, it is argued that a compensated acidosis is present, in so far that there is a lowering of the alkaline reserve of the organism. Pritchard has pointed out that various causes may lead to acidosis, malnutrition, defective hygiene, infection, indigestion, vitamine deficiency, ill-regulated food balance, disordered metabolism, and, as Sir Arbuthnot Lane is constantly insisting, intestinal stasis. Acidosis, of course, does not always manifest itself in the form of rickets, but is likely to do so in infants and young children in which the soil is favorable. Another point upon which Pritchard lays stress is that excess of feeding, or rather relative excess of feeding, leads more frequently than insufficiency of food. Dr. Amy Hodgson, writing in the *Lancet*, Nov. 5, last, and whose investigations seem to lend support to Pritchard's views, declares that a careful study of work on the calcium metabolism in rickets reveals nothing to negative Pritchard's theory.

Tuberculosis in Dublin.—The chief tuberculosis officer for Dublin, Dr. P. J. Murray, has recently issued his report for the year 1920. Morbidity from tuberculosis in Dublin during the past six years has diminished steadily. In 1915 there were in the city 1,543 deaths due to the disease, of which number 1,193 were owing to pulmonary tuberculosis. The numbers decreased every year until in 1920 they had fallen to 820 and 615, respectively. The scheme at present embraces (1) a dispensary; (2) a sanatorium, and (3) a hospital for chronic or advanced cases. There are also arrangements for treating the various forms of surgical tuberculosis in the city hospitals, and subsequently, if necessary, in convalescent homes. Dr. Murray is in favor of the provision of an institution for the treatment of children suffering from pulmonary tuberculosis. He holds the view that the topographical and climatic conditions of Dublin have little influence on the incidence of the disease, which is greatly more influenced by the conditions under which the poorer inhabitants are obliged to live. He has found domiciliary treatment of less value than institutional because of the deplorable housing conditions of many of the working people, conditions which render any attempt at isolation of no avail.

Lead Poisoning and Industrial Hygiene.—At the Royal Institute of Public Health, Sir Kenneth Goadby gave recently the last of a course of lectures on "Problems of Public Health in Relation to Industrial Hygiene." He took lead poisoning as his subject. He said that lead workers, as a rule, did not show a high phthisis rate, while house painters showed a slightly exaggerated rate, probably owing to the fumes of turpentine they inhale. No man could inhale more than two milligrams of lead per day without danger. Lead entered the body in the form of dust, and the solution of the trouble would be the devising of mechanical methods to keep the dust away from the worker.

Obituary.—Sir Arthur Pearson, well known the world over as a business man and a philanthropist, died under peculiarly distressing circumstances at the age of 55. Blind himself for several years, his name will live as one who taught the blind not to consider blindness an affliction and as a handicap to be battled with and overcome. His death, indeed, was an indirect consequence of his proud and stern self-reliance. One of his proudest boasts was that even in the small affairs of daily life, if his tie were well arranged and his shave well done, he owed it not to a valet but

to his own hands. He was in the custom of going to his bath alone and he met his death in a curiously pathetic manner. He was getting into his bath when he slipped and fell and struck his head with so great force that he became unconscious and, when in this condition, was drowned in the water of his bath. He need not have died, and he would not have died, if he had not insisted on absolute reliance on himself. He founded the Blinded Sailors' and Soldiers' Hospital at St. Dunstan's in Regent's Park, London, and this was one of the most successful of all the institutions for the relief of war disability. The Fresh Air Fund, established in connection with *Pearson's Weekly*, a magazine founded and owned by him, was the means of giving a very large number of town and slum children a holiday in the country.

3. Post-Typhoid Chondritis of Ribs: Two Cases: Typhoid Bacillus.—Frederic J. Cotton describes the case of a man, 42 years of age, who, following a severe attack of typhoid fever with relapse, developed a swelling over the fifth costal cartilage left of the sternum. Aspiration of the tumor yielded pus which on culture showed the *B. typhosus*. The tumor was excised and the cavity cauterized with carbolic acid followed by alcohol. In spite of persistent and efficient disinfection the Eberth bacillus persisted in the wound for four months, finally necessitating a second operation. The sinus was excised and all cartilage and perichondrium removed from the sternum to the end of the rib. The would was left wide open and allowed to heal by second intention. The case is of interest because of the dogged persistence of the Eberth bacillus and because it is an absolutely clean-cut case of infection in a small area deeply within the rib cartilage, manifesting itself outside only after a perforation and the formation of a secondary abscess. The second patient was also a man, 42 years of age, who on admission to the hospital because of a painful swelling in the left chest, gave a history of typhoid fever five months before, complicated with pneumonia and "pleurisy." After cleaning out and disinfecting this abscess there was failure to close as in the first case. In order to clear up the infection, which was shown to be due to typhoid bacillus, it was probable that removal of the whole cartilage, as was done in the first case, or the progressive removal of layer after layer with a carbolic disinfection for each layer, and a pressure dressing at the end of all, might still be necessary. This was a case, not of infection within the rib-cartilage, but in the perichondrium or thereabouts. These relatively common typhoidal rib-cartilage infections often subside, but always they are slow. In one instance coming under the writer's observation there were abscesses in both tibiæ which did not come to operation until seven years after the typhoid fever. In this case a pure *B. typhosus* culture was obtained from one tibia.

Vulvovaginitis.—A. K. Paine, in a study of 91 cases of this condition in children treated in the special clinic for gonorrhea in women conducted by the Boston Dispensary, reaches conclusions somewhat as follows: (1) That probably less than 10 per cent. of all the cases of vulvovaginitis in children are caused by the gonococcus of Neisser. (2) That of the remainder, about one-half (essentially "epidemic" in type, the numerous cases occurring simultaneously in institutions, schools, or family groups) is caused by mucus membrane infecting organisms such as are factors in the production of common colds, nasal infections, conjunctivitis, and the like. (3) That the remaining cases are about equally divided etiologically between those caused by masturbation and those caused by flagrant disregard of the habits of cleanliness. (4) That the duration of the infection (including the rare but definite gonorrheal type) is relatively short, provided always that a causative factor in the nature of some irritation is not continuously active or that irritation is not supplanted by the greater irritation of an "active treatment." (5) That the term "vulvovaginitis" is not accurately descriptive inasmuch as the vagina is rarely, at least extensively, involved, unless vaginal treatment has been employed. (6) That the cardinal principle of treatment should be cleanliness secured without in itself producing mechanical or chemical irritation. Segregation of isolation of these vulvitis cases is not advised except as better treatment may be secured in the early part of the affection, for if epidemic vulvitis represents something in the nature of an autoinfection from infected nasal secretions, obviously the case to case infection is via the latter, and occurring probably before the vulvitis as an individual sequela appears, segregation becomes unnecessary because too late.

4. Preliminary Communication Regarding Steinach's Method of Rejuvenation.—Harry Benjamin, having visited Steinach's clinic, finds on his return to this country that the greatest errors exist regarding this method. It is frequently confused with gland transplantation, for instance of the monkey gland and with all forms of gland treatments, and unfortunately has been deprived of the scientific seriousness which it nevertheless deserves. The point that so far has not been brought out with necessary clearness is, that by the Steinach operation the patient is given a more or less massive and continuous dose of his own gonadal hormone instead of the hormone of another human being or a monkey. Whenever the endocrinologist would prescribe a gonadal preparation this operation in one of its forms would theoretically be indicated. The effects following the operation have to be explained by the development of the gonadal hormone and (this is the most important point) its influence on all other glands with an internal secretion. The operation is therefore a treatment for all symptoms due to senility such as arteriosclerosis, hypertrophy of the prostate, eunuchoidism, mental depression and cases of dementia praecox where gonadel insufficiency is suspected to be the cause. The results that are obtained in cases of senility, especially premature senility, are so striking and remarkable that they may most accurately be described as rejuvenation. The theory of vasoligature is that it causes atrophy of the spermatogenetic apparatus of the tests—an atrophy from pressure and inactivity. The interstitial tissue, the hormone bearing apparatus, takes its place by way of hypertrophy, and this hypertrophy is accomplished by those clinical events which equal more or less a rejuvenation. The

success or failure of the operation depends not only upon the ability of the puberty gland to renew or increase activity, but also upon the response that the whole endocrinological system of the patient will give to the renewed output of gonadal hormone. After citing a number of cases, the writer expresses the opinion that on the same principle a treatment for women is also possible, not by a surgical procedure, but by the use of *x*-rays in such a way that the sensitive generative tissue of the ovary is destroyed by properly selected doses and this would cause hypertrophy of the more resistant cells that form the ovarian hormone. Many gynecologists have observed that women who were treated with *x*-ray for fibromyomata of the uterus, and other conditions, showed such remarkable general improvements that they were described as new youth. The success was ascribed to cure or improvement of the disease, but in the light of Steinach's discovery they deserve a different interpretation.

8, Clinical Studies of Lethargic Encephalitis.—Rufus S. Reeves reports in detail six cases of lethargic encephalitis, from which he concludes that the protein character of the symptoms of lethargic encephalitis makes the diagnosis in the atypical cases very difficult. Laboratory and clinical findings make it evident that mild and abortive cases and carriers play an important part in the spread, especially during an epidemic. The four most prominent symptoms are eye conditions, lethargy, fever, and atypical spinal fluid. The filterable virus has a selective action on the brain stem. Definite symptoms of cerebral disturbance are seen in patients one year after the disease. Lethargic encephalitis must be differentiated from syphilitic meningitis, in which the positive findings are fluid under pressure, positive Wassermann, positive Kernig's sign, some rigidity of the muscles of the neck and a patient in continuous stupor, who, when aroused, cannot understand what is said to him; from tuberculous meningitis, where there is also fluid under pressure and containing many lymphocytes and tubercle bacilli, positive Kernig's, some rigidity of the muscles of the neck, tuberculous history, physical findings, and dissociation between temperature and pulse; from anterior poliomyelitis in which the spinal fluid is cloudy, contains many polymorphonuclear and eosiniphile leucocytes and the meningococcus, positive Kernig's, stiffness of the muscles of the neck, exaggerated patellar reflexes, positive Babinski and ankle clonus; from cerebral abscess, in which the eye examination shows choked disc, the leucocyte count is high, there is a marked pleocyte count and at times cloudy spinal fluid, hectic temperature, usual history of primary focus and projectile vomiting; from brain tumor, in which there is usually a history of slow onset with headache and vomiting.

Acute Yellow Atrophy of the Liver Complicating Acute Appendicitis.—Moses Behrend points out that yellow atrophy of the liver is a rare disease, many clinicians of large experience never having observed a case. In all, five cases have come under his observation. The symptoms were practically alike in all of them. The symptoms come on rather stealthily. There is slight gastrointestinal disturbance, soon followed by vomiting of a mild character. Malaise and the lack of a desire to take food are noted, followed almost immediately by a slight jaundice, without pain, which is very characteristic because of the absence of pain and the less intense yellowish discoloration seen in obstruction of the bile passages. Delirium usually ensues and portends a fatal termination. The case reported is that of a girl, 16 years of age, who at the time of admission to the hospital, had been sick for two days, suffering from all the cardinal symptoms of acute appendicitis. At operation on the following day, on account of acute bronchitis, chloroform anesthesia was used. The appendix was gangrenous and the pelvis contained pus. The abdomen was drained. For the first twenty-four hours the temperature ran a normal course. The following morning the skin was slightly jaundiced, there was a rise of temperature, the pulse was fairly good, though a little rapid. The patient vomited a little during the day, became delirious, and died on the morning of the third day. The diagnosis of acute yellow atrophy of the liver was confirmed at autopsy. The liver was pale yellow in color, not especially smaller in size. Two factors could have caused the fatal complication, namely, a late poisoning due to the chloroform anesthesia or the serious appendiceal infection. The cause of the complication seems to point rather strongly to the anesthetic.

2. **Telangiectatic Splenomegaly.**—Douglas Symmers describes three cases in which the only common clinical factors are anemia with leucopenia and massive enlargement of the spleen. He draws the deduction that there is a systemic disease characterized by extensive proliferation of the endothelium of capillaries, particularly involving organs that belong to the hematopoietic group—the spleen, bone marrow, liver and lymph nodes. The most striking feature of the disease is found in the massive enlargement of the spleen, due to profuse proliferation of the lining endothelium of its smaller vascular channels, with the production of new capillaries and the subsequent formation of telangiectases, identical or related histological changes being apparent in other organs of the hematopoietic system, and occasionally in organs beyond this system. In the spleen and lymph nodes the proliferative changes in the capillary endothelium appear to rise in vessels that are native to the part. In other instances the same sort of cells may be seen infiltrating and distending capillaries, notably in the skin, bone marrow and liver; but whether these cells are produced *in situ* is not apparent. The disease is neither frankly neoplastic nor strictly inflammatory, but presents features incident to both and, perhaps, is best included in that group which occupies a position intermediate between neoplasia and inflammation, taking its place, in this regard, with Hodgkin's diseases, mycosis fungoides, Cohnheim's pseudoleucemia, Sternberg's leucocarcoma, Gaucher's splenomegaly, and the like.

3. The Clean Inunction Treatment of Syphilis with Mercury.—H. N. Cole, A. J. Gericke, and Thorald Sollmann present a preliminary clinical study on the basis of which they draw the following conclusions: (1) In treating syphilis by means of mercurial inunctions, probably the only mercury absorbed is that part of the mercurial ointment which is rubbed into the hair follicles, and entrances of the sebaceous and sweat glands. Hence, all superfluous ointment remaining on the skin may be cleansed off immediately after the inunction without lessening the mercurial effect. (2) From forty-four clinical cases of syphilis treated by this technic, we feel that we have been able to prove this clinically. (3) As a result of our findings we feel that, in the future, mercurial inunctions need not be discarded because of the unpleasant considerations in regard to their use, namely, uncleanliness, liability of discovery, and causing of a folliculitis. (4) Mercurial inunctions following the technic that we advise are to be recommended in the treatment of syphilis as a distinct advance in the therapy of this disease. The technique employed was as follows: Four grams of the official Unguentum Hydrargyi U. S. P. was rubbed in for thirty minutes. At the end of this time all mercury remaining was thoroughly removed from the skin by the free use of benzine and cotton. With these patients a different spot was used each night for at

least six nights in order to prevent chances of irritation of the skin and so that the criticism could not be raised that mercury was absorbed through the irritated skin.

6. **Investigation on the Activities of Infective Hookworm Larvæ in the Soil: Preliminary Report.**—William W. Cort, Donald L. Augustine, and George C. Payne have conducted this study, which brings out facts quite at variance with present ideas in regard to the life of infective hookworm larvæ under natural conditions. They have found in both their field and laboratory studies that it is a common occurrence for mature hookworms to lose their sheaths while living in the soil, and to continue their lives in the unsheathed condition. In regard to the migrations of infective hookworm larvæ in the soil the opinion has become current that they actively move out of the place of development and that a small center may give rise to extensive soil infestation. These observations indicate that as far as their own activities are concerned, the infective hookworm larvæ are difinitely limited to the place of development. It is generally believed that infective hookworm larvæ may live in the soil for periods of more than a year. These observations both from field and laboratory experiments show that under tropical condition hookworm larvæ in the soil die out quickly, and that an area even of very heavy soil infestation will soon become safe after the elimination of soil pollution.

7. **Nonsurgical Drainage of the Biliary Tract: Its Usefulness, Diagnostically and Therapeutically.**—Frank Smithies, Clyde Karshner, and Richard Bartlett Oleson present certain facts regarding 679 drainages or the attempted carrying through of such, in 309 individuals. There were 169 females and 140 males. The youngest patient was 6 years of age, the oldest 69. There were 19 patients experiencing acute or subacute biliary tract disease; the remaining patients were chronic sufferers who appeared for relief of various types of digestive upsets. While the writers are still undecided in respect to many points, they feel that they have made sufficient advance to warrant the statement that they now regard metapyloric biliary tract drainage as being the most important single procedure available for the elucidation of gall tract and liver anomalies. The following indications are suggested as indicating gall tract disease as revealed by metapyloric drainage: (1) No appearance of bile-stained fluid in duodenal contents, after repeated magnesium sulphate solution stimuli. (2) A quantity of common duct bile greater than 25 c.c., in which bile are found abnormal sediments—blood, pus, increased cholesterin, pigment crystals, calculi, epithelium, mucus, and bacteria. In this series of cases when biliary tract disease was present the average quantity of common duct bile was 49 c.c. Intermittence of discharge of common duct bile on repeated intraduodenal stimuli is of useful import. (3) Absence of gall-bladder bile following repeated magnesium sulphate stimuli indicates some break in the neuromuscular reflex, cystic duct obstruction from whatever cause, gall-bladder atony or overdistention, inspissated of calcareous gall-bladder contents, gall-bladder tumor or benign or malignant adhesions involving the gall-bladder duct. (4) Securing gall-bladder bile in quantity greater than 75 c.c. or less than 20 c.c. of different types on repeated intraduodenal stimuli; gall-bladder bile intermittently discharged, especially when in the specimen there are abnormal sediments. Dark colored bile specimens do not necessarily come from diseased gall-bladders; neither does it follow that bile not dark colored is free from anomalies and does not come from gall-bladders. Dark color indicates commonly stagnation on some part of the biliary tree from the liver lobule to the papilla of Vater, or abnormal function on the part of the liver itself due to local or systemic upsets. It has been proven by the authors in their practice that metapyloric biliary drainage has a place in the treatment of affections of the biliary tract. In ailments which are of recent inception or where pathological damage precludes hope of successful surgery, by preventing bile stasis, by attempting to eradicate infections and by striving to improve heptic functions, the procedure is of service. It is a mistake, however, to attempt to relieve obstructive lesions, known calculi, tumors and the like, when by surgical endeavor more logical and positive relief may be quickly brought about.

10. **A Note on the Venereal Spirochetosis of Rabbits: A New Technique for Staining Treponema Pallidum.**—Hideyo Noguchi has made observations on rabbits found among the normal stock of the Rockefeller Institute which presented spontaneous lesions of the anogenital region containing an organism resembbling *Treponema pallidum*. More recently six rabbits just purchased in Pennsylvania were found to have similar lesions. The organisms found in these lesions are somewhat different from the *Treponema pallidum* and may be designated *Treponema cuniculi*. The staining properties of these two varieties of Treponema are similar. A new procedure has been worked out by Miss Evelyn B. Tilden in Noguchi's laboratory by which both *Treponema pallidum* and *Treponema cuniculi* can be stained very distinctly not only with Giemsa solution but also with basic dyes, such as gentian violet and fuchsin. The procedure promises to be of practical value in the routine diagnosis of syphilis, when the dark field is not available, because of its simplicity. A buffer solution containing formaldehyde (1 part of formaldehyde solution in 9 parts of phosphate buffer solution is used as fixative, the scraping or tissue emulsion being suspended in a small amount of the buffered formaldehyde solution and the mixture allowed to stand for at least five minutes (the longer the fixation the better the results; the organisms remain well preserved for at least two or three weeks). Thin films are made on clean slides, dried in the air, the film surface is flooded with a saturated alcoholic solution of gentian violet or fuchsin, or with Stirling's solution of gentian violet such as is used for Gram's stain, and the slide is almost immediately washed in running water and air dried.

5. Domiciliary Treatment of Bone and Joint Tubercle. W. C. Rivers.
6. A Note on Guelpa's Method in the Treatment of Gout and Glycosuria by Fasting and Purging. Henry Lunn.

1. **An introduction to the Study of Aphasia.**—S. A. Kinnier Wilson discusses the anatomical basis, the physiological and psychological mechanisms, and the clinical varieties of aphasia. He demonstrates that appreciable advantages are secured by regarding aphasia as part of a wider cerebral syndrome, namely, that of apraxia and agnosia. If aphasia is to be considered a disorder of symbolic thinking, it is important to grasp the fact that such disorder may reveal itself where no words, as such, come into the question at all. Yet unless some explanation is offered such as that provided by the conception of apraxia and agnosia, the limits of aphasia will be stretched unjustifiably. A patient who dresses himself wrongly or makes mistakes, or "short-circuits" in performing any act such as lighting his pipe, shows a disturbance which cannot by any legitimate mean be regarded as aphasia, but the disorder is certainly one of agnosia or apraxia. By the utilizations of these modern conceptions the way is paved for a more comprehensive insight into cerebral activities, both on the receptive and on the executive side.

2. **Eclampsia and Its Incidence.**—R. H. Paramore outlines a new conception of eclampsia, based on the previous conception that intraabdominal pressure is a vital force, dependent upon the body wall muscles, and fundamentally related with general, and more particularly, with visceral metabolism. Many considerations show that intraabdominal pressure is intimately related with general metabolism, and its increase in pregnancy has been demonstrated. Differences in the form of the abdomen, especially in evelopment of its muscular walls, and in the degree of its distension, indicate that differences occur in intraabdominal pressure at corresponding periods of pregnancy.

It is reasonable to suppose that the pressure, as pregnancy advances, becomes greater in strong muscular women than in those who are weak. It is in the cases of strong muscular women that the toxemia of pregnancy appears more commonly. It is to be expected that in primigravidæ greater pressures should occur, other things being equal, than in pregnant multiparæ; similarly it is obvious that tight lacing must cause greater pressures than in those who go loose. This latter fact affords an explanation of the frequency of ecalmpsia in unmarried pregnant women. There are other types the proneness of which to eclampsia is remarkable, namely, the cases of multiple pregnancy, hydramnios, concealed accidental hemorrhage and hydatidiform mole. These conditions have in common one factor, namely, that the size of the uterus is considerably larger than it should be. This increased size is a factor affecting intraabdominal pressure. Many considerations show that intraabdominal pressure is intimately related with general metabolism. Intraabdominal pressure also interferes with the blood flow to the liver and kidneys. The blood reaching the convoluted tubules of the kidneys has first to traverse the capillary networks forming the glomeruli, with the possibility of escape by way of the medulla. Clearly if the blood is obstructed by the cortex and escapes by the medulla, the selectiveness of the necrosis in eclampsia is explained. Similarly if the blood flow through the liver is sufficiently impaired, liver inanition and patchy necrosis becomes intelligible. The question is whether an obstruction due to pressure and sufficient to cause such changes actually occurs in these secondary capillary areas. The writer believes that a study of intraabdominal pressure and of the incidence of eclampsia warrant the acceptance of this idea.

3. **Value and Comparison of Renal Efficiency Tests.**—John D. Comrie finds that the combination of the estimation of blood-urea, of urea concentration in the urine, and of phenolsulphonephthalein excretion, gives reliable information as to the functional condition of the kidneys. The blood-urea estimation should form a preliminary investigation. If it rises above 50 mg. per 100 c.c. of blood the condition is serious. If it is found to be persistently over 100 mg. recovery is not likely, and death will probably take place within a year. In uremia it may exceed 200 or 300 mg. before death. The blood-urea may be normal while a marked degree of renal impairment exists; but in such cases the prognosis is usually favorable. The blood pressure shows no constant relation to the amount of blood-urea; though when blood urea is permanently high the blood pressure is usually high. The phenolsulphonephthalein test, in the writer's experience, is the most valuable individual test. An excretion, which takes place chiefly in the first hour and which in two hours reaches 70 per cent., or over, gives a good prognosis so far as the kidney function is concerned. An excretion of 50 per cent. in two hours in either renal or cardiac cases is compatible with complete restoration of health. An excretion of about 30 per cent. is compatible with prolonged life though on a low plane of vitality. When the excretion does not rise above 20 per cent. in spite of treatment, death within a year may be expected. The urea-concentration in the urine test is simple, harmless, and gives valuable information. The amount fluctuates more in individual cases than does the phenolphthalein excretion. A urea-concentration of over 3.5 per cent. indicates a satisfactory renal function; over 2 per cent. it is compatible with a fair degree of health; if it persists below 2 per cent., in spite of treatment, it is unsatisfactory.

3. **The Relation of Carcinoma to Infection.**—W. Ford Robertson has developed certain culture methods by the aid of which he has been enabled to observe facts regarding the behavior of bacteria which, although new, have attracted little attention. One of these facts is that many bacteria that we regard as aerobes commonly assume, when their attack is prolonged, an anaerobic habit of growth, and can be cultivated only under anaerobic conditions. This applies, for example, to such important pathogenic species as *Micrococcus catarrhalis*, the gonococcus, *Streptococcus pyogenes*, *Streptococcus fecalis hemolyticus*, and several types of diphtheroid bacillus. If a bacterium of this kind establishes itself in an epithelial cell and multiplies, the cell may die on account of the toxic action that ensues. It is far from likely that in every instance the cell will succumb. One action of bacterial toxins on cells is to stimulate growth. It is possible that some types of bacteria, if established within an epithelial cell, would have chiefly this effect. With these facts and possibilities before him the hypothesis suggested itself to the author that the rods he has observed within cancer cells by means of the pallidum methylene violet method might be anaerobic bacteria that had established themselves within the epithelial cells, and that the continued proliferation was due to these bacteria. He has tested this hypothesis in various ways during the past two years and submits evidence to support it which he claims is, to put it mildly, sufficient to arrest attention. There is evidence to support the belief that there appears to be a race of anaerobic bacteria, comprising several species belonging to the large diphtheroid group or to the closely allied streptothrix group, which are capable of infecting epithelial cells and maintaining within them a parasitic existence. There are some rounded or oval bodies that may occasionally be seen in the cultures which cannot be called either bacilli or micrococci, but which are not incompatible with the polymorphism of some of the higher bacteria, especially the streptothrices. It is probable that bacteria of other groups are capable of acting in the same way. If this is so cancer may have to be regarded as dependent upon a special mode of bacterial attack, rather than upon a specific infection. Invasion of the cell would appear to be effected, as a rule, by bacteria of comparatively vigorous growth and easy to cultivate, but when these bacteria adapt themselves to purely parasitic intracellular growth they become comparatively feeble and extremely difficult to grow in culture media. Tumors can be produced in mice by both the vigorous and the teebly-growing strains. Focal reactions can be obtained in some cases, success probably depending upon the vaccine having been prepared from the same species as that in the case. The possible diagnostic value of such reactions is a question which must be left for future investigation to determine.

7. **Decapsulation of the Kidney in Bright's Disease.**—T. H. Sanderson-Wells reviews the literature on this subject and reports a case in which this procedure has been successful at least for the time being. He states that the published cases demonstrate that success is possible even *in extremis*, and some remarkable complete recoveries are recorded. Although the physiological and pathological findings are adverse, the clinical results prove that from the patient's point of view the outcome is often satisfactory. The writer's patient is quite settled on this point. Moreover, he is probably characteristic of many in that though not completely cured and possibly doomed eventually to die of the disease, the operation has been justified by the result. The operation deserves consideration under two conditions: (1) As an emergency in eclampsia, uremia, suppression of urine, etc. The more desperate the extremity the more certainly it should be discussed, and cases have been snatched from apparently impending dissolution. (2) In chronic cases, when medical treatment has failed after a thorough trial. In both the above classes the heart and arteries should be reasonably sound, which probably means that most success will be obtained in the first half of life.

Book Reviews.

EYE, EAR, NOSE AND THROAT NURSING. By A. EDWARD DAVIS, A.M., M.D., Professor of Diseases of the Eye in the New York Post-Graduate Medical School and Hospital, and BEAMAN DOUGLASS, M.D., Professor of Diseases of the Nose and Throat in the New York Post-Graduate Medical School and Hospital. Second revised edition, with 32 illustrations. Price, $2.50. Philadelphia: F. A. Davis Company, 1920.

THOUGH primarily written for the use of nurses and students, this little book is of considerable value to those practitioners who are compelled to do their own nursing. It abounds in hints and points that are not to be found in any textbook, because they are considered as matters of fact and too elementary to dwell upon. Such little procedures as the proper instillation of eye drops, rapid and painless eversion of the upper lid, application of drops or solids to the lids, syringing an ear, douching the nasal chambers, etc., will be taken note of by the intelligent patient, and due credit or otherwise given to the physician. We find the authors' treatment of lime burns of the eye somewhat at variance with the present conception of such burns as propounded, for example, by Würdeman, who employs extensive douching with water, the first that comes to hand, picking and wiping out of the lime, later using ammonium chloride solution. On the subject of chalazion mention might be made of excision, an operation often to be preferred to curettage, especially in large growths. The authors' advice to keep the packing after an operation for deflected septum for 48 hours (p. 292) will be subscribed to by very few operators, most of whom remove it within 12 or the longest 24 hours. Our experience, and we believe that of most operators, does not substantiate another statement that "after tonsil operations sepsis is of extremely frequent occurrence;" with the modern methods of tonsillectomy we do not find it so.

DIE BEDEUTUNG DER VERSCHIEDENARTIGEN STRAHLEN FÜR DIE DIAGNOSE UND BEHANDLUNG DER TUBERKULOSE. Mit dem Robert Koch-Preis für Tuberkuloseforschung gekrönte Monographie. Von Dr. RUBEN GASSUL, früher am Berliner Universitätsinstitut für Krebsforschung. Mit 2 Kurven. Leipzig: Georg Thieme, 1921.

THIS booklet is practically a bibliographic review of the various radiations used in the diagnosis and treatment of tuberculosis as practised at the Berlin University Institute for the Tuberculous. The roentgen diagnosis of tuberculosis is briefly rehearsed, throughout which copious references to German investigators are presented. The second part outlines the prevalent German conception of radiations in the treatment of tuberculosis including the quicksilver quartz light, the *x*-ray, radium and mesothorium and finally the combination of two or more of these agencies. Two interesting charts are presented. The first shows seven groupings of tuberculosis—Incipient lung infiltration; long-standing lung infiltration; Areas of consolidation in the lung; small lung cavities; large lung cavities; miliary tuberculosis, and various forms of surgical tuberculosis. Four means of diagnosis are chartered. These are roentgen ray diagnosis, physical diagnostic methods, diagnosis through the use of tuberculin, and combined diagnostic methods. In incipient lung infiltration combined methods seem to give a greater number of correct diagnoses, the *x*-ray and physical diagnoses giving about an equal percentage of positive diagnoses though both are slightly less sensitive than the combined methods. This approximately is the case with the miliary tuberculosis and with various forms of surgical tuberculosis. For the other groupings doctored by this author the *x*-ray is charted as showing the greater percentage of correct diagnoses, combined methods slightly less, physical methods alone still less. For all types tuberculin diagnosis of tuberculosis is always less sensitive and generally more unsatisfactory than any of the three methods already discussed. The second chart deals with the various forms of ray therapy in which it is shown that for various types of tuberculosis (lung, laryngeal, urogenital, etc.) radium, surgical intervention and spontaneous healing are generally less effective than heliotherapy, roentgen ray, combined methods, and quartz light.

INFORME CORRESPONDIENTE AL AÑO DE 1920 que el Director de Sanidad Nacional Presenta al Ministro de Relaciones Interiores. Caracas: F. J. Camejo & Co., 1921.

THIS annual health report of Venezuela is a large quarto volume of nearly 400 pages. Among the individual sections are the reports of the sanitary engineers and physicians, the movement of epidemic and contagious diseases, inspection of pharmacies, inspection of schools, service of vaccination, inspection of laboratories, statistics, inspection of leper hospitals, financial report, service of publications, service of material and transportation, inspection of houses, inspection of markets, etc., service of disinfection and deratisation, inspection of drainage and garbage disposal, etc., etc.

MEDICAL ELECTRICITY, RÖNTGEN RAYS AND RADIUM, With a Practical Chapter on Phototherapy. By SINCLAIR TOUSEY, A.M., M.D., Consulting Surgeon to St. Bartholomew's Clinic, New York City. Third Edition. Thoroughly Revised. Price $10. Philadelphia and London: W. B. Saunders Co., 1921.

To those familiar with the earlier editions of this work no words are necessary to describe its excellence. To those who are not familiar with the work the advice may be given to become so. It is a most exhaustive treatise on all subjects comprised under the title, viz: Static electricity, dynamic electricity, physiological effects of electricity, electropathology, electrodiagnosis, ionization, electromagnets, electricity in diseases of the nervous system, high-frequency currents, phototherapy, fluoroscopy and radiography, roentgenotherapy, and radium. All these subjects are treated of in great detail and in a very instructive manner. The illustrations are numerous and well made. The book can be recommended as one of the best guides to the therapeutic employment of electricity and radioactivity that we have, second in practical utility only to actual experience.

PRACTICAL PSYCHOLOGY AND PSYCHIATRY. For Use in Training-Schools for Attendants and Nurses and in Medical Classes, and as a Ready Reference for the Practitioner. By C. B. BURR, M.D., Medical Director of Oak Grove Hospital (Flint., Mich.) for Mental and Nervous Diseases; Member of the American Medico-Psychological Association, of the American Medical Association, of the American Neurological Association; Fellow of the American College of Physicians; Foreign Associate Member of Société Médico-Psychologique of Paris, etc. Fifth Edition, Revised and Enlarged, with Illustrations. Philadelphia: F. A. Davis Company, 1921.

FIFTH editions do not beg for encouragement. This little work of scarcely more than 250 pages continues to stand for the same high ideal, the same practicality, the same sound judgment in its specialty that it has always represented. The chapters on psychology and forms of insanity have been revised and new material added; likewise a new chapter on the prevention of insanity has been made a feature of this book. It amply fulfills its reason for success and at the same time is pleasurable reading.

A MANUAL OF SURGICAL ANATOMY. By CHARLES R. WHITTAKER, F.R.C.S. (Ed.), F.R.S.E., Senior Demonstrator of Anatomy, Surgeons' Hall, Edinburgh; Lecturer on Biology, Extra-Mural School of Medicine, Edinburgh; Examiner in Biology, Royal College of Surgeons, Edinburgh. Third Edition, revised and enlarged. Price $3.50. New York: William Wood and Co., 1921.

THIS is one of the smallest of the works on Surgical Anatomy; at the same time, it is certainly the most readable and will readily serve as an introduction to the larger (and drier) works on the subject. The author has been particularly happy in his choice of anatomical facts and in the various groupings; and the numerous tables, diagrams and illustrations all tend to make this little book one of unusual value to the student. Of course, the larger standard works will have to be studied later; but a perusal of the present volume will certainly smooth the path.

Society Reports.

SOUTHERN MEDICAL ASSOCIATION.

Fifteenth Annual Meeting, Held at Hot Springs, Arkansas, November 14, 15, 16, and 17, 1921.

THE PRESIDENT, DR. JERE L. CROOK OF JACKSON, TENNESSEE, IN THE CHAIR.

Early Diagnosis and Treatment of Joint Tuberculosis.—Dr. JOHN T. O'FARRALL of New Orleans said sufficient care was not taken in making a diagnosis in the average case of early joint tuberculosis. The average general practitioner and general surgeon were not fully awake to the importance of early and accurate diagnosis and treatment in such cases, nor were they fully conscious of their responsibility as related to the functional end result. The treatment of joint tuberculosis required not local treatment of the affected part alone, but rigid and long continued constitutional treatment. Protection and extension of tuberculous joints should last over a period not less than two years, especially as regards weight bearing. The promiscuous opening of tuberculous abscesses and haphazard curetting of sinuses was extremely bad surgery. The end result striven for should not be ankylosis, but a functioning joint. It was unfair to hope for such a result if weight bearing was allowed upon an actively diseased bony structure.

The Limits of Orthopedic Surgery.—Dr. EDWARD S. HATCH of New Orleans stated that a man who expected to specialize in orthopedic surgery should first spend several years in the general practice of medicine and should have a thorough surgical training. He should be very familiar with normal skiagraphic anatomy and should be well schooled in mechanics, in the details of manufacture of all types of deformity apparatus as well as the designing of such apparatus. He must be a mechanic, a surgeon, and a roentgenologist before he attempted to limit his work to orthopedic surgery, and, as Dr. Baer says, must have patience, perseverance, and optimism. The amount of borderline work that came to the orthopedic surgeon would be governed by his skill in handling the operative side, together with his accurate and careful work along mechanical lines that his orthopedic training had given him. The American Orthopedic Association at the meeting in 1920 adopted a resolution stating that the scope of orthopedic surgery should include the framework of the human body, the bones and joints and abnormalities of the motor apparatus. This would include: (1) Congenital and acquired deformities of the spine and extremities. (2) Infantile paralysis after the acute stage. (3) The deformities of adult paralysis. (4) Stiff ankylosed joints. (5) Torticollis. (6) Disabilities of joints, such as rupture of crucial ligaments, injuries to the semilunar cartilages, snapping hip, slipping patella, fractures, etc. The orthopedist would be consulted in severe and complicated fractures and in diseases in and about joints. In his orthopedic clinic advice was constantly being sought in compensation insurance injury cases by those who had received inadequate treatment from the insurance surgeons. These were usually fractures, sprains, and joint injuries, to which superficial treatment only had been given, and the patients realized that they were unable to resume their former occupations, though they had been discharged as cured by their doctor. Being unable to pay for service, they applied to the orthopedic clinic, because they had learned that the orthopedic treatment helped them to get back to their work earlier.

X-Ray Study of the Lumbosacral Spine.—Dr. ARCHER O'REILLY of St. Louis said that abnormalities and variations in the lumbosacral region were very common. In some cases, however, variations in a minor degree were due to distortions as a result of the position of the patient when the *x*-ray picture was made. Variations of the lumbosacral spine were not confined to patients with back symptoms, but were also seen in about 50 per cent. of persons who had never had back symptoms. It was probable that in these cases the spine was inherently weak, and that eventually backache or strain might develop. Irregularity at the lumbosacral articulation was very common, not only in persons suffering from backache, but also in those who had never had back symptoms, so that the surgeon, in cases of injury, must be very guarded in stating that there had been displacement or fracture as a result of the accident.

Operative Treatment of Certain Fractures.—Dr. EDWIN W. RYERSON of Chicago stated that Whitman's method in the treatment of fracture of the neck of the femur was simple and was followed by a high percentage of good results. It could rightfully be called an operative method, because it involved the actual reduction of the fracture, usually under an anesthetic. The technique should be perfectly understood by general practitioners, for they were the men who took care of most of the fractured hips. The patient was placed upon a pelvic support which had a perineal post. If this was not at hand, a folded sheet might be placed between the legs and tied to the head of the table. The legs were pulled upon by assistants or traction apparatus until they were of equal length, the operator lifting the trochanter upward at the same time. The leg was then rotated slightly inward. These maneuvers approximated the fractured surfaces of the bone. Both legs were then spread widely apart in abduction to the extreme limit possible. This brought the trochanter against the upper rim of the acetabulum and stabilized the fracture. A long plaster-of-Paris spica bandage was then applied over sufficient cotton padding with the leg held in firm abduction. The cast was worn for at least three months, and no weight bearing was allowed for eight or nine months longer. The patient was gotten out of bed as soon as possible and was encouraged to walk about on crutches. This method of treatment was applicable to the great majority of cases of fracture through the neck of the femur (intracapsular type), no matter how old or how fat the patient might be. The union might not be absolutely accurate from an anatomical viewpoint, but it was almost certain to be excellent from a functional standpoint. He believed that very few fractures would require open operation if they had had competent mechanical treatment, but that very few communities at present were provided with the requisite appliances and materials for the proper treatment of many of the common and disabling forms of fracture. All communities should be as well equipped for the treatment of fractured femurs as they were for the treatment of diphtheria or appendicitis.

Treatment of Fractures of Long Bones.—Dr. W. BARNETT OWEN of Louisville stated that the method of treating fractures which he wished to submit for consideration was one devised by the late Dr. H. H. Grant of Louisville, Kentucky, in 1915, and was known as the "gimlet fixation method." Personally, he had employed this method in eleven cases—two fractures of the humerus and nine of the femur. A mild infection occurred in one case of fracture of the femur. Operation was performed at the Louisville City Hospital, necessitating later the removal of a small sequestrum. Union of the bone was firm and subsequent function good. The patient was an acute alcoholic, had a four plus Wassermann (blood), and his general condition was exceedingly unfavorable when admitted to the hospital. The results in the other ten cases were entirely satisfactory—firm union, good position, and perfect function. This method of operation and fixation of the fragments appeared to be more simple than other plans suggested and was equally as efficient. The gimlet method afforded outside control of internal conditions. It was a simple and efficient method of maintaining reduction. Proper selection of suitable cases for treatment by this method was important. In no case should the patient be subjected to open operation if the fracture could be successfully treated by the closed method. Restoration of function was the point of prime importance in the treatment of fractures. Rigid aseptic technique, adequate assistance, and proper equipment were essential to success.

Difficulties and Errors Before and After Antimalaria Campaigns.—Dr. C. C. BASS of New Orleans summarized these as follows: Difficulties before the campaign were to get the people sufficiently interested to want the campaign; to secure the necessary appropriation of funds to support it; to secure a suitable staff of competent, well trained persons to carry out the campaign.

The errors before the campaign were failure to secure the definite promise of full cooperation on the part of the physicians who practised in the area; failure to plan to employ to best advantage and in accordance with their relative importance under the existence circumstances all available measures, including especially quinine control. Difficulties after the campaign were the return to former conditions as a result of neglect and loss of interest; changing population resulting in introduction of many infected people. The errors after the campaign were the discontinuance of the campaign too soon or too greatly reducing activities.

Control of Typhoid in Rural Communities.—Dr. ALECK P. HARRISON of Austin, Texas, stated that typhoid fever was one of the oldest diseases known to man. It was confined to man alone and not found in the lower animals. Its etiology and methods of transmission were thoroughly understood. Infection came only from an infected individual ill with the disease, or a carrier, through infected water, milk, or food. The infection must be swallowed. There was a constant source of infection in rural districts, the open-back privy, the open, unprotected wells, the unscreened houses being the chief sources of danger. Typhoid might be controlled and eradicated by educating the masses of people, educating the carriers, building sanitary privies, using pumps instead of open wells, screening the houses, properly treating patients, and protecting all water, food, and milk supplies, and lastly by rendering a large proportion of the population immune by vaccination. He emphasized the great importance in typhoid control, and all health work, of making a strong appeal to the common sense of the people to help protect themselves against preventable diseases.

Essentials of Successful Leadership for Public Health Work on a County Basis.—Dr. S. W. WELCH of Montgomery, Alabama, stated that the primary requirement for successful leadership for public health work on a county basis was native ability to deal with people, supplemented by a medical education and an understanding of the operation of law in human conduct, particularly with relation to rural psychology. A detailed and comprehensive knowledge of scientific phases of the health field seemed less essential to the health officer in the early beginning of health organization than ability to anticipate popular needs and harmonize divergent interests. Candidates for these positions should be intelligently recruited from every possible source. Their qualifications for the task should be observed under favorable conditions as might be found and the question of their fitness decided without prejudice. The extent to which effective supervision by the State Board of Health might contribute to an uninterrupted field of results in county health work and to the continued individual growth of professional personnel was dependent upon a set of conditions in which were inextricably interwoven problems of organization and administration, such as: Wise and fortunate selection of personnel; subordination of unduly self-seeking motives in functional bureaus and their staffs; clear enunciation of objections and fundamental principles; precision of adjustment of each individual to his place in the State organization; sureness with which the whole is moved by a will to think and act as a unit. Only, he believed, as we approached this ideal should we be able to even approximate our full measure of usefulness as a State health agency.

Soil Pollution, a Public Health Problem of Today.—Dr. E. L. BISHOP of Nashville, Tennessee, said that in the selection of a type of privy for community installation in rural districts attention should be given to two general factors: (1) The soil formation and ground water level, having in mind that the vertical distance between an area of pollution and ground water was the important one, the horizontal distance being of relatively little importance except in the case of limestone fissures and other natural or artificial openings. A recent study indicated that soil reaction had an important bearing on the survival of pathogenic bacteria; hence, this factor must also be considered. (2) Ability to secure community application of the type selected, taking into account the accessibility of materials, the economic status of the community to be served, and individual willingness to buy the degree of protection decided upon. The fundamentally essential thing was to do the best we could with what we had; to get dangerous matter off of the surface of the ground, place it where it was least dangerous, and the best advantage could be taken of natural processes; quicken, if possible, those processes, but make any compromise that lessened the exciting evil.

Fish as an Antimosquito Agency.—Dr. J. A. LEPRINCE of Memphis stated that the value of *Gambusia* to the people of the South should be very much more commonly known than it was today. It was the duty of the health officer and the sanitarian to see that they got it. If we were ready to do our share, the editors of the public press in our section were ready to assist right now. Each county health officer in the malaria belt should make it his business to see that a fish hatchery was established at the county seat, where those who came into town on Saturday afternoons could and would notice it. In some towns a concrete tank could be placed in the court house square, *Gambusia* installed therein, and the attention of the public invited to it by an appropriate sign. Also, owners of permanent stock ponds generally allowed them to use their property as hatcheries. In Tampico, Mexico, Dr. A. Cuaron, representing the Mexican Federal Health Service, surrounded each of the large concrete fountain basins in the public plaza, where the crowds gathered, with a four foot high picket fence, painted in the national colors—red, green, and white—and kept the tanks empty and everybody guessing what it was all about. Later he turned on the water, stocked the tanks heavily with *Gambusia*, and had appropriate signs attached telling the public that these fish would drive yellow fever out of the city if the public would ask for them and use them in cisterns and all other water containers to prevent mosquito production. The public response was all that could be expected. The plan was a huge success. In many counties there were permanent ponds near well traveled good roads. These ponds could easily be stocked at small expense and large signs used to tell the rural public that the county health officer could supply them with the fish. In many cases the women's clubs, chambers of commerce, etc., could and would gladly help to finance the making and installing of this large advertising sign. The wise county health officer was aware that the public was of the opinion that "seeing is believing," and knew that the public could both see and feel the effect of the absence of the mosquito pest and of the usual seasonal malaria. If correctly planned, mosquito control measures could be made to be a lever for other classes of rural sanitation that were not yet so readily measured by the public eye. Some of the progressive county health officers were applying this idea with excellent, visible results. The county superintendents of schools could be interested, and jars of fish kept in each school. Final school examination papers could contain a question or two about *Gambusia*. There should be properly labeled exhibits of *Gambusia* at every county agricultural fair. This exhibit could be used to induce farmers to breed this fish in their stock ponds. Many stock ponds in impervious soils went dry in the summer time. A health officer could often, by proper suggestion, get the farmer to deepen the pond at one point sufficiently to retain some water throughout the period of drought. This would keep the fish alive, provide water for stock, and help to prevent malaria transmission. It could be done in the season of the year when other work was not pressing. A drag scraper and one or two mules could do this work in a short time and give permanent beneficial results. The *Gambusia affinis* was present and waiting to help the health officer, waiting to work twelve to fourteen hours a day for him throughout the entire mosquito season without pay. The important question was, were the health officers ready, or were they only waiting? Would they give the little assistance necessary to overcome the barriers placed by nature in front of this small fish of big sanitary importance?

Prostatectomy; Pre- and Postoperative Treatment.—Dr. RAYMOND THOMPSON of Charlotte, N. C., said that all patients requiring prostatectomy should have special preoperative treatment and postoperative care, and especially those who had a large amount of residual urine infection. Blood pressure readings carefully taken at stated intervals afforded a valuable guide as to the proper time for operation. The clinical picture

and laboratory findings were of the greatest importance as an index to the patient's condition.

The More Common Causes of Chronic Urinary Obstruction in Male Children.—Dr. A. W. FRONTZ of Baltimore stated that congenital valves of the posterior urethra and *Spina bifida* were the most frequent causes of chronic urinary retention in children. The diagnosis was not difficult. As the internal vesical sphincter and prostatic urethra were frequently widely dilated in both conditions, as shown by cystography, developmental defects of the lumbar and sacral spine should always be eliminated. The treatment of obstruction from congenital urethral valves was most satisfactory if instituted before the development of serious lesions of the upper urinary tract.

Spina Bifida with Associated Diverticulum of Bladder (Urachus) and Pyonephrosis.—Dr. JOSEPH H. SMITH of Memphis said that in *Spina bifida* there was failure to close of the neural arches of the third, fourth, and fifth lumbar vertebra; some contraction and distortion of the pelvic bones; curvature of the spine over this region; supernumerary or accessory first lumbar rib; meningocele over the sacro-lumbar region; marked trabeculation of the bladder in its entirety, distorted left urethral orifice and orifice of diverticulum (urachus); diverticulum extending far up in the right hypogastrium, contents approximately 500 c.c., forming a large fluctuating tumor when distended; pyonephrosis of the left kidney and a large pelvis with abrupt termination of the distention downward of the thorium shadow which led one to believe there was an obstruction due to an aberrant blood vessel; a lower shadow superimposed upon the pyonephrotic shadow was due to dilatation of the ureter (hydroureter). He recommended left nephrectomy (extraperitoneal), closure of the diverticulum, with drainage of the sac without removal through a suprapubic opening. The bladder should be stripped far back from the parietal peritoneum.

The Problem of Chronic Infection of the Prostate.—Dr. A. NELKEN of New Orleans said that hematogenous infection of the prostate, besides that due to tuberculosis and to lues, occurred more frequently than was generally taught. Usually infection of the prostate was secondary to infection of the urethra. Statistics were variable, depending in some measure on the mental bias, the industry, and the opportunity of the compiler. It was his opinion, founded on his own experience, that the prostate was involved in 85 per cent. of all cases of gonorrheal urethritis and in upward of 50 per cent. of all cases of nonspecific infections of the urethra. For many years his coworkers and himself had made routine slide examinations of prostatic secretions in cases of urethral infections. Many cases had been checked by cultural methods, some few by the complement fixation test for gonorrhea. While it was the rule to find the specific organism of Neisser in acute gonorrheal infection of the prostate, it was his experience that it was rare to identify this organism in chronic prostatitis. The longer established the disease, the less the probability of finding gonococci. He had in his records but one single case with a reliable history of infection of more than two years' duration in which he was able to find an organism that appeared both on staining and culturally to be the gonococcus.

Postoperative Care in Surgical Conditions of the Kidney.—Dr. H. W. E. WALTHER of New Orleans stated that in considering the management of these cases the phases that most attracted his interest were (*a*) the care of the wound; (*b*) the care of the patient; (*c*) means of preventing complications; and (*d*) the treatment of complications after they arose. Urinary fistula did not commonly occur where the pelvis had been sutured or where the capsule and perirenal fat had been brought together over incisions in the renal cortex. Should urine come from the wound after the seventh day, urethral catheterism should be practiced to establish patency. As to the dressings employed, plain dry sterile gauze, held in place by adhesive strips, in not too bulky a quantity, changed as required, was all that was necessary. The dictum of Lower, that postoperative hemorrhage could be discovered more promptly through light dressings than through ponderous ones, applied equally as well to kidney surgery as it did to surgery of the prostate. The immediate after-care of the patient as related to shock deserves careful attention. Keeping the patient quiet, warm, away from draughts, guarding against pain by hypodermic administration of morphine sulphate, pantopon, papaverine, or the oral administration of some anodyne, and establishing diuresis by giving water freely either by mouth, by hypodermoclysis, by proctoclysis, or by infusion would do much toward restoring the patient. Hemorrhage at operation, which could not be arrested by hemostatic forceps and ligature, was best controlled by packing. Whether the gauze pack employed should be dry or saturated with one of the thromboplastin preparations still remained a mooted question. He had used coagulin a number of times with most pleasing results in cases of intractable bleeding from wounds following operations on the kidney.

Some Observations on the Treatment of Gonococcal Arthritis in the Male.—Dr. NEIL MOORE of St. Louis said that gonococcal arthritis was the result of focal infection and should be treated as such. Hard work on the part of the physician with proper cooperation of the patient over a sufficient length of time was necessary for complete relief. Foci of infection in the male were usually always located in the prostate and seminal vesicles. In the female, if the focus of infection would be demonstrated in the more superficial adnexa then it would seem that a complete salpingohysterectomy should be considered. Injections of foreign proteins undoubtedly were of definite value in the treatment of these infections. Local treatment of the involved joint was of secondary importance.

The Murmur of Mitral Stenosis in the Presence of Auricular Fibrillation.—Dr. NEUTON S. STERN of Memphis said there was a definite period of time in the heart cycle between the closing of the semilunar valves and the opening of the auriculoventricular valves. There was a similar interval of time between sounds corresponding to these events, *i. e.*, the second heart sound and the diastolic murmur of mitral stenosis. The diastolic murmur extended more or less throughout the diastole, depending on the stage of stenosis. There might be a presystolic murmur, or presystolic accentuation of the diastolic murmur when the auricles beat normally. In auricular fibrillation, the presystolic element was lost, and in the long pauses was replaced by a silent period. In auricular fibrillation, the diastolic murmur might fade out and be succeeded by silence, or might continue into the following first sound, depending upon the length of diastole. In auricular fibrillation, the constant interval between the second sound and the diastolic murmur persisted.

A Study of the Glucose Tolerance Test in the Obese.—Dr. JAMES E. PAULLIN of Atlanta said that he had selected for his study twenty-six cases, all showing from 10 to 80 per cent. overweight. In so far as possible, patients who exhibited other conditions which might influence the study were not used, although included in this number were six cases with arteriosclerosis and a slight hypertension. Before accepting them he determined as nearly as he could that the kidneys showed no essential damage which would influence the character of the reaction. In only one case did he feel that the kidney had been damaged sufficiently to influence the test, yet he did not think that there was sufficient damage to cause the response given. He also realized that practically all obese patients had at one time or another been accused of having some endocrine disorder which caused or contributed to their obesity. He felt that perhaps with these various disorders at times one might lose sight of the secretion from the islands of Langerhans, and neglect to diet and exercise these individuals instead of feeding them polyglandular extracts. He did not believe that the glucose tolerance in his cases was markedly influenced by any of the hypo-glandular inactivities. He fully realized that the number of cases studied was quite small and any definite statement made concerning this condition was subject to a large percentage of error; at the same time, he felt quite strongly that the results were insignificant and that by a study of the glucose tolerance test, even in so small a number of patients, he had detected at least five prediabetics, and two of the five had definitely developed diabetes. The test was simple, reliable, and of a great deal of value in stressing the importance of dietary therapy in these cases.

Food Allergy as a Cause of Abdominal Pain.—Dr. W. W. DUKE of Kansas City said that it was well known that humans and animals might become sensitive to alien bodies of many varieties. When this was the case they reacted whenever they came in contact with the body to which they were sensitive. The gastrointestinal mucosa might become hypersensitive to an article of food, with the result that the patient experienced severe abdominal pain, often associated with nausea and vomiting, whenever he ate the food to which he was sensitive. These alimentary symptoms were in many cases the sole striking manifestations of the reaction. Individuals sensitive to certain articles of diet, such as shad-roe, lettuce, honey, strawberries, cabbage, tomatoes, paprika, etc., usually gave a history of occasional attacks of abdominal pain and digest upset. As a rule, they were free from digestive disturbance between attacks. Individuals sensitive to the commoner articles of food, such as milk or eggs, had more frequent attacks of pain, and were often subject to chronic indigestion as well. The symptoms of food allergy might simulate somewhat those of a surgical lesion in the abdomen, and an error in diagnosis could be made unless this condition was kept in mind. Food allergy was observed more frequently in individuals who had organic lesions in the gastrointestinal tract or its appendages than it was in normal persons. Severe attacks of food allergy had acute appendicitis as a sequel in two cases, and surgical intervention was required.

The Rationale of Digestive Therapy.—Dr. ERNEST H. GAITHER of Baltimore stated that his most encouraging results had been obtained by the use of various combinations of iron, arsenic, and strychnine, given hypodermically. His personal experience was not sufficient to warrant an opinion as to the efficacy of the intravenous method of drug application. Postoperative digestive cases called for the exercise of the greatest discretion and closest attention, but as a class they were the most neglected with which one had to deal. Because a lesion had been eradicated was no reason to disregard well established principles in treating a damaged organ or organs involved primarily or secondarily; yet surgeons frequently prolonged the period of convalescence, and sometimes defeated the purpose of an operation, by permitting a gastrointestinal patient to return quickly to a general and often improper diet. In the hands of certain investigators, lavage of the duodenum and drainage of the gall bladder by the newer methods seemed to have been productive of good results, but their value in digestive therapy had not been conclusively established as yet. In true digestive neurosis where an absence of organic change was proven, the best results were obtained by prescribing a well regulated, properly balanced general diet, and by psychotherapy with hygienic, dietetic, and medicinal principles applied symptomatically. To tamper with the stomach in these cases was fatal from the standpoint of successful treatment, for after all the prerequisite was the reeducation and upbuilding of the asthenic, irritable nervous system.

Glossopyrosis.—Dr. K. HEBERDEN BEALL of Fort Worth, Texas, presented four cases in which a constant burning of the tongue was the sole symptom, and in which the physical examination was negative. In all of these cases there was an absence from the dietary of meat and whole milk. Two cases were lost sight of; the other two were relieved of the burning of the tongue by the addition of meat and whole milk to the diet.

Significance and Diagnosis of Cardiac Anginal Pains.—Dr. D. D. PAULUS of Oklahoma City said that pain, often of a more or less paroxysmal character, was a frequent finding in heart disease independent of angina pectoris. These pains were really protests from an overworked, inflamed, or degenerated heart and might arise from the heart as well as the aorta. Whatever their source, pains over the precordial area demanded a thorough investigation of cardiac function, etc., unless the condition present was obvious. Only by full and complete kowledge of the atypical symptoms of angina pectoris were we able to recognize many of the minor manifestations of this condition.

A Case of Sporotrichosis.—Dr. C. M. GRIGSBY of Dallas stated that sporotrichosis was a chronic infection characterized by both internal and cutaneous lesions and caused by one of the various forms of the parasitic fungi of the sporotrichosis group. There were four clinical forms: (1) The disseminated gummatous form characterized by small firm nodules which broke down. (2) The ulcerative type resembling tuberculous cutis. (3) The localized type which resembled a large gumma. (4) The extracutaneous forms, ulcerous lesions of mucous membranes, osteomyelitis, etc. The differential diagnosis lay mainly between tuberculosis cutis, syphilis, and mycosis. The diagnosis was made by bacteriological examination of the contents of the lesions.

A Discussion of the Newer Methods in the Treatment of Diabetes.—Dr. ELLIOTT P. JOSLIN of Boston stated that improvement in the care of patients with diabetes would come from physicians having them in their own hands. One could not expect to lower a hospital mortality of 2 per cent. much, if any, but one must lower home mortality, so that patients under sixty years of age, as well as over sixty, might look forward to the completion of their expectation of life. If the duration of diabetes accidentally discovered by insurance companies was twelve years, it lay in the power of every practitioner in the United States not only to duplicate their results for similar age periods, but to surpass them. The doctor should detect diabetes not by accident but by design. Thereby he would gain an advantage because treatment could be begun at a still earlier stage. The incipient case of diabetes was the easy one to treat, but the obligation to treat the early case thoroughly and well was even greater than in tuberculosis. It was imperative that clinicians should control their various types of treatment by follow-up methods over periods of years. There were advantages in all kinds of treatment. The one who originated a new policy was the one best able to find the fault in it. Tracts regarding treatment, etiology, and classification were all that were needed to clear up many other diabetic mysteries. Observe, he did not say discoveries, but the simple accumulation of facts which, when compiled, would convince and point out the true path. Neither to the general practitioner nor to the clinician were the anxious eyes of the parents of the little diabetic child turning today, but to the laboratory worker. We expected the laboratory men to do for diabetes what had been done for myxedema. Were we doing what we could to encourage them and to foster their laboratories? Did we tell patients to help them? Practitioners, clinicians, scientists—diabetes is a disease which needs the help of all of you.

The Treatment of Cancer of the Uterus by Radium.—Dr. LOUIS FRANK of Louisville said that cancer of the uterine body treated by total oblation of tubes, ovaries, and uterus yielded curative results which one could not hope to surpass by any other form of treatment. All borderline cases should be treated with radium. Late cases might be improved and palliated by radium as by no other means at our command. If the five-year period of curability was to be accepted as indicating a cure, then the results of radium treatment surpassed by far those obtained by the profession at large in the treatment of cancer of the cervix by surgical means.

The Undescended Testicle.—Dr. M. E. STOUT of Oklahoma City stated that the disturbance from the diminished internal secretion, together with the psychic phenomena was usually of more serious consequence than the physical condition. No operative procedure should be endorsed that interfered with the internal secretive properties of the testicle, and its removal should not be done except for the same cause that a normally located testicle would be removed. Judging from his own experience with thyroids and other observers' reports, the Bevan operation reduced the internal testicular secretion. Orchidopexy was the operation of choice when it could be accomplished without tension on the cord or disturbing the circulation. Orchido-celeoplasty cured the physical condition without the loss of the testicle or its internal secretion.

Retrodisplacement of the Uterus with Suggestions Regarding Their Proper Treatment.—Dr. W. T. BLACK of Memphis said that congenital retrodisplacements rarely required treatment. Simple displacements following a recent pregnancy could often be corrected by the wearing of a properly placed pessary. One should

select with judgment the type of operation best suited to be used in the various conditions encountered in retrodisplacements. It was an unpardonable mistake to select the same technique for all cases. A great many needless operations for this condition were being performed in his opinion.

Remarks on Surgery of the Gall Bladder, with an Analysis of 512 Cases from the Surgical Clinic of the University of Virginia Hospital.—Dr. W. H. GOODWIN of Charlottesville, Va., said that the operative mortality in cases of cholecystostomy in this series was 5 per cent. and in cholecystectomy 3.3 per cent. It was quite true that cholecystostomy was the operation of choice in a few cases where the prognosis was very poor and the more formidable operation of cholecystectomy thought to be unwise. Of the patients traced who had cholecystostomy done, 71.5 per cent. were cured, 23 per cent. improved, and 5.2 per cent. unimproved. Of those who had cholecystectomy done, 88 per cent. were cured, 9 per cent. improved, and 3 per cent. unimproved. No one should dogmatically say that cholecystectomy ought to be the operation of choice in all gall-bladder disease, but on account of the better immediate and final results and the shorter and more comfortable convalescence of cholecystectomy, he believed that operation should be done in the vast majority of cases. Deaver said that 65 per cent. of recurrences could be prevented by removal of the gall bladder. Cholecystostomy certainly had a field of usefulness in the very ill patient with infected gall bladder complicated by jaundice. In the very ill patient with stone in the common duct and deep jaundice cholecystostomy might be relied on to tide the patient over the emergency, and later the stone could be removed with much less risk to the patient. Crile emphasized the importance of slow drainage in the very ill jaundice patient by suturing a tube in the gall bladder, or common duct, if the condition necessitated this latter procedure, and establishing a fluid tight system of drainage by clamping the tube and releasing the clamp at frequent intervals. The jaundice case frequently had a very much delayed coagulation time, and Crile advised that a transfusion of blood or an intravenous infusion of 0.2 per cent. calcium chloride be done previous to operation and that this procedure be repeated after operation.

Some Observations on Prostatic Surgery.—Drs. F. L. CARSON and E. L. YEAKEL of Shawnee, Oklahoma, stated that the hazard of operation was less than the dangers of repeated catheterization. One of the chief dangers in prostatic work was the preliminary withdrawal of urine. In average hands the two-stage operation was the method of choice.

Acute Intestinal Obstruction.—Dr. GEORGE A. HENDON of Louisville said that the percentage of mortality was in direct proportion to the number of hours that elapsed between the onset of the symptoms and the performance of the operation. In cases obstructed one hour there was shown 1 per cent. mortality; two hours, 2 per cent. mortality; three hours, 3 per cent. mortality, etc. In searching for the obstructed bowel not over five minutes should be employed, and Moynihan had pointed to the fact that the obstructed loop of intestine was almost invariably to be found in the pelvis. His own experience bore testimony to this observation; also to the fact that the collapsed portion of the intestine invariably occupied the pelvic cavity. It was a notable fact that a bowel which was strangulated and became gangrenous outside the abdominal cavity was not so frequently fatal in its consequences as the same amount of intestine becoming gangrenous within the cavity. Hence the relatively low mortality rate of strangulated hernia. In every case morphine hypodermically, sufficient in quantity to control pain, should be administered after the diagnosis had been decided on. Under no circumstances should any effort at purgation be resorted to in the presence of an acute intraabdominal lesion. All attempts in this direction should be limited to the use of a simple enema.

Extrophy of the Bladder.—Dr. W. W. GRANT of Denver said that the extraperitoneal implantation of Bergenhem-Peters, modified by transplanting ureters and trigone intact through one anterior rectal incision was less dangerous and more quickly done and was the operation of choice. The two-stage operation was neither necessary nor desirable. The importance of preserving the blood supply and the valve action of the ureters in transplanting the ureters and base of the bladder intact was of distinct value as to the immediate success of the operation and in the prevention of ascending infection, and was the operation of choice. In advanced malignant and tuberculous disease of the bladder, the Coffey-Mayo operation and technique was the operation of choice. The rectal cloaca, as a urinary reservoir, was ample without operative effort to increase it. The rectal mucosa became almost as tolerant of the presence of urine as the normal bladder, and, he believed, the danger of uremia from bowel absorption of urine was very slight. Urinary control was essential to any successful operation on the bladder, and it was effectively and satisfactorily obtained in the above operation.

A Review of 300 Cases of Breast Disease.—Drs. IRVIN ABELL and STUART GRAVES of Louisville stated that the material upon which the review was based consisted of 300 cases coming under observation up to and including 1920; 139 were carcinoma, two were sarcomata, and 160 presented various types of non-malignant disease. Of the carcinomata, 136 occurred in women and two in men; both of the sarcomata occurred in women, and of the 160 cases of benign disease, 159 occurred in the female and one in the male breast. Of the 297 women, 198 were married and 99 unmarried, a proportion of two to one; 100 of the carcinomata occurred in married and 36 in unmarried women, a proportion of almost three to one; 98 cases of benign diseases were observed in married and 61 in unmarried women, a proportion of three to two; of the three men, two presented carcinoma and one benign disease. The preponderance of breast disease in married women doubtless found its explanation in the changes dependent upon and following lactation. In the earlier carcinoma cases of this series, recurrence in or near the site of incision was not infrequently noted. Later, with the employment of wide skin resection, recurrence at this site had been rare. The supraclavicular glands, lungs, and mediastinum had been the most frequent sites of secondary deposits. This had been noted with such frequency that they considered it advisable in all cases to ray the chest before operating. Of deposits in the osseous system, the ribs and sternum presented the greater number, with four in the vertebral column and three in the femur. Metastasis to the liver and abdominal organs had been infrequent. Of the twenty-eight cases of conservative amputation traced, all were well; of the thirty-four cases of excision of tumors traced, five reported recurrence; of the five, two were chronic mastitis with adenoma, one chronic cystic mastitis, and two adenomata, one of which was single and one multiple with two tumors in the right breast and one in the left.

Spinal Anesthesia.—Dr. J. R. GARNER of Atlanta said that any surgeon who would try spinal anesthesia, using stovaine as the medium of producing same, and following the technique outlined, would find five points to recommend its use as having a decided advantage over inhalation anesthesia, namely, ease and rapidity of administration; minimizing of surgical shock and marked amelioration of any existing shock; marked safety over gas-oxygen, chloroform, or ether anesthesia in cases showing cardiac, renal, or pulmonary lesions and in cases already in shock; absence of many of the disagreeable postoperative symptoms generally following the administration of a general anesthetic, and last, but not least, a most grateful patient.

The Roentgenological Diagnosis of Gastric Ulcer.—Dr. RUSSELL D. CARMAN of Rochester, Minn., said that since operation offered the only hope of cure in this affliction, it was of the utmost importance that the diagnosis be made early and before the lesion had become inoperable. The earliest stage at which the condition could be recognized by the rontgen ray depended on varying circumstances. Among these were the size of the lesion, its situation, its character, the thoroughness of the examination, and the examiner's keenness of observation and judgment. Very small lesions on either curvature were susceptible of demonstration, and he had occasionally been able to discover them in various parts of the stomach at a very early stage. Cancers high in the cardia might escape detection unless a screen examination was made with the patient recumbent.

Growths on the posterior or anterior wall required careful palpatory fluoroscopy with views at various angles. Nonobstructive lesions in the pyloric portion of the stomach, unless they deformed one or the other curvature, were sometimes peculiarly hard to find. The feasibility of operation in a given case of gastric cancer depended on many factors apart from those disclosed by the roentgen ray. Among these were the skill of the operator, the general condition of the patient, and the presence or absence of metastasis in regions where it could not be discovered roentgenologically. Yet, by showing the situation and probable extent of the neoplasm, the roentgen ray furnished data which should be considered in deciding the question of operation.

X-Rays in the Diagnosis of Pulmonary Tuberculosis.—Dr. JOHN D. MACRAE of Asheville, N. C., emphasized certain things in *x*-ray diagnosis of pulmonary tuberculosis. Stereoscopic lung plates were the most valuable method and all other methods were secondary in value. Interpretation of *x*-ray of the lungs should be made independent of clinical findings in the case. The radiologist and clinician should hold conference on each case examined and compare notes on their separate findings. Terminology and technique should be standardized. Study of the "normal" chest in order to interpret plates of the pathological should be resorted to. Postmortem examination on tuberculous subjects should be made as often as possible, with the purpose of correlating densities in the *x*-ray plates with actual lesions in the lungs. The careful application of these notes would improve the diagnosis in pulmonary tuberculosis tremendously.

(*To be continued.*)

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

STATE BOARD OF MEDICAL EXAMINERS OF WYOMING.

Cheyenne, June 6-8, 1921.

(*Continued from vol. e, p.* 1099.)

THERAPEUTICS.

1. Give treatment for lobar pneumonia.
2. Give management of a case of malignant hypertension.
3. Give management of a case of scarlet fever, and your treatment of two of the most common complications.
4. Give treatment for pernicious anemia.
5. Give treatment for epidemic meningitis.
6. Give treatment for chorea.

MATERIA MEDICA.

1. Name a cerebral stimulant, a cerebral depressant, a cardiac stimulant, a cardiac depressant, a respiratory stimulant, a respiratory depressant, a vasomotor dilator, a vasomotor contractor.
2. Give the most important alkaloids of the following drugs: Nux vomica, jaborandi, opium, digitalis, belladonna.
3. What is the action of digitalis, and would it be indicated or contraindicated in heart block.
4. Define the following: Diuretic, diaphoretic, soporific, anthelmintic, analgesic, hypnotic, hemostatic, cholagogue.
5. Upon what part of the bowel do the following act: Magnesium sulphate, aloes, oleum ricini, strychnine, jalap.

PHYSICAL DIAGNOSIS.

1. Give differential diagnosis between cardiac dilatation and hypertrophy. (*b*) What do you understand by hemic murmur?
2. Diagnosis of aneurysm of the thoracic aorta.
3. What are the methods of physical diagnosis? (*b*) Give technique.
4. Give significance of general retraction of the abdomen.
5. Name general causes of distention of the abdomen.
6. Give the technique of splenic examination.
7. Give the general causes for leucocytosis. (*b*) Give the general causes for leucopenia.
8. Give the diagnosis of paresis and locomotor ataxia.
9. Give the most common valvular heart disease, also the most dangerous. (*b*) Give the physical diagnosis of loss of compensation.
10. Give the diagnosis of tumors of the brain.
11. Give the physical diagnosis of neuritis.
12. Give the physical diagnosis of the stages of pneumonia.

ANSWERS.

THERAPEUTICS.

1. The *treatment of lobar pneumonia* "depends entirely on the type of case, and the condition of the patient. Routine treatment is the worst of all treatments. Answer the following questions before prescribing: Is the patient full-blooded, and is there a full bounding pulse? Is the pulse feeble, irregular, or intermittent?

"In the first case, in a young and previously healthy adult, if there be cyanosis, or signs of dilatation of the right heart, blood-letting to the extent of a few ounces may perhaps relieve the strain, but more generally treatment should be directed to maintaining the strength from the outset.

"In the latter case we can hope for nothing from a depressing treatment, so stimulants must be resorted to, such as alcohol, ammonium carbonate, egg and brandy mixture, quinine, ether, etc. The giving or withholding of alcohol depends upon its effect upon the pulse; should the pulse rate fall and the tongue become moist it may be continued. In asthenic cases, strychnine hypodermically is necessary from the outset, and normal saline may be given by the rectum or by the skin. Oxygen inhalations are used where there is cyanosis, but it is doubtful whether they have saved many lives. When there is evidence of failure of the heart (weakness of the second pulmonary sound, etc.) digitalis should be resorted to. Many prescribe it from the outset.

"The diet should consist of milk, beef tea or broths, white of egg, and so on. The patient should be as little moved as possible, and the bed pan must be used. As in other fevers, an airy room and good nursing are essential.

"Remember that narcotics are not well borne in respiratory embarrassment as a rule. Chloral should be avoided, but *if pain be excessive* a hypodermic injection of morphine does *more good* than harm, notwithstanding that theoretically morphine is contraindicated. It should not be given later than the first few days of the illness. The pain may also be relieved by poultices, which, however, are of doubtful use if carelessly made, or by application of ice. Cold packs applied to the trunk only, and frequently repeated, are very useful in relieving both pain and fever. Depressant antipyretics are to be avoided.

"The results of *serum treatment* are not unequivocally encouraging, but vaccine treatment would seem to be of better promise. Where possible, an autogenous vaccine should be used."—Wheeler and Jack's *Handbook of Medicine.*)

2. In *cases of malignant hypertension,* the patient should be impressed with the need of moderation in all things—work, play, exercise, and food. Constipation must be prevented; alcohol, tea and coffee should be forbidden; meat must be forbidden, or very little allowed; milk is to be taken; plenty of rest is indicated; sometimes venesection is useful; the chief drugs used are the nitrites, and iodides. The general health must be attended to, and conditions such as pyorrhea, and syphilis must receive appropriate treatment.

3. *Treatment of scarlet fever and its complications.*—The treatment is that of infectious fevers in general, and in addition: "1. *Serum treatment.*—Serum from convalescents, injected in doses up to 20 c.c., has sometimes proved successful. Good results have also been obtained with polyvalent antisreptococcic sera (*i.e.* sera prepared from several different strains of cocci). 2. The danger of spreading the disease is greatest during the desquamative period. Isolation must therefore be kept up for at least six weeks from the onset, or till all desquamation and discharges (nasal, aural, etc.) have ceased. 3. A minimum amount of nitrogenous food, to avoid irritation of the kidneys. This

caution does not affect milk, which may be freely used. 4. Daily toilet, tepid sponging, or tepid baths. 5. Inunction of oily antiseptic preparations into the skin, to prevent dissemination of the desquamating scales. 6. Examine the urine daily for signs of nephritis. 7. The condition of the ears must be carefully watched. *Complications.—Arthritis* demands warm and sedative applications. Wrap the joints in cotton wool; alkalies are better than salicylates, as the latter tend to irritate the kidneys. *Throat.*—Ice to suck; antiseptic sprays; glycerin of carbolic acid; warm applications externally. *For the severe types.*—Avoid caustic applications; relieve pain by cocaine solutions; internally, tincture of ferric chloride, with free administration of ammonia; quinine, either alone or with ferric chloride. Stimulants may also be required. Nasal feeding often gives much relief. *Nephritis.*—Milk diet, hydragogue purgative (avoid mercurials), hot air baths, hot packs, etc., according to the severity of the dropsy."—(Wheeler and Jack's *Handbook of Medicine.*)

4. *Treatment of pernicious anemia:* "Fresh air, rest, and a diet as liberal as the digestive powers of the patient will permit are requisite. Warm salt baths and massage are valuable adjuvants to internal treatment. The teeth should receive careful attention. If there be gingivitis or pyorrhea alveolaris, antispetic mouthwashes should be used at frequent intervals. Arsenic is the most valuable drug. It may be given in the form of Fowler's solution, the dose being gradually increased from 2 or 3 to 15 or 20 minims three times a day. Iron is rarely of service. Bone-marrow is sometimes efficacious. Inhalations of oxygen have been recommended. Appropriate anthelmintic remedies should be given, of course, in the cases in which intestinal parasites are present. Digestive disturbances are often benefited by the administration of dilnted hydrochloric acid and a bitter."—(Stevens' *Practice.*)

5. Epidemic Cerebrospinal Meningitis. *Treatment* includes the use of Flexner's serum (injected into the subarachnoid space after about 40 c.c. of the spinal fluid has been withdrawn). The patient is to be kept in a dark room, with his head elevated (but not flexed) and an ice bag applied to head and spine. Nutrient enemata may be required; both bowels and bladder need to be watched. Nervous symptoms may demand an opiate or chloral; urotropin is said to be of service.

6. Chorea. *Treatment.*—"(1) *Rest in bed* is the first and essential point of treatment. (2) Arsenic in increasing doses, cod-liver oil, abundant food, and careful attention to the bowels. Antipyrin or phenacetin in increasing doses is also useful. Salicylates are of value only in rheumatic complications. When the movements are very severe, chloral may be freely given. (3) As soon as convalescense seems established, allow the patient plenty of fresh air and gymnastic exercises."—(Wheeler and Jack's *Handbook of Medicine.*)

MATERIA MEDICA.

1. *A cerebral stimulant*, caffeine. *A cerebral depressant*, opium. *A cardiac stimulant*, digitalis. *A cardiac depressant*, aconite. *A respiratory stimulant*, strychnine. *A respiratory depressant*, aconite. *A vasomotor dilator*, alcohol. *A vasomotor contractor*, adrenalin.

2. *Alkaloids of nux vomica.*—Strychnine, brucine.

Alkaloids of jaborandi.—Pilocarpine, isopilocarpine.

Alkaloids of opium.—Morphine, codeine, narceine, narcotine, thebaine, papaverine.

Alkaloids of digitalis.—None. (The *glucosides* are: digitalin, digitalein, digitin, digitonin, digitoxin.)

Alkaloids of belladonna.—Atropine, hyoscyamine, hyoscine.

3. Digitalis. *Physiological action:* It is a gastrointestinal irritant, it slows the rate of the heart, prolongs diastole, increases the force of the heart, it contracts the blood-vessels, and causes a rise in blood pressure, it also acts as a diuretic.

Therapeutic use: Digitalis is indicated in diseases of the heart: (1) when the heart action is rapid and feeble, with low arterial tension; (2) in mitral lesions when compensation has begun to fail; (3) in nonvalvular cardiac affections; (4) in irritable heart, due to nerve exhaustion. Digitalis is contraindicated in diseases of the heart: (1) in aortic lesions when uncombined with mitral lesions; (2) when the heart action is strong, and arterial tension high. Digitalis is also a diuretic; and it is also used in some forms of nephritis, exophthalmic goiter, pneumonia, chronic bronchitis, etc.

Partial heart block is exaggerated by digitalis; digitalis is, therefore, contraindicated. In *complete heart block* digitalis can do no further harm.

4. *Diuretic* is any agent which increases the flow of urine.

Diaphoretic is any agent which promotes the secretion of sweat.

Soporific is any agent which induces sleep.

Anthelmintic is any agent which expels or destroys intestinal worms.

Analgesic is any agent which relieves pain.

Hypnotic is an agent which induces sleep.

Hemostatic is any agent which checks a hemorrhage.

Cholagogue is any agent which induces a flow of bile.

5. *Magnesium sulphate* acts upon the colon.

Aloes acts upon the descending colon and rectum.

Oleum ricini acts upon the small intestine.

Strychnine acts upon the nerve plexuses in the small intestines.

Jalap acts upon the small intestine.

PHYSICAL DIAGNOSIS

1. Cardiac Hypertrophy: "*Inspection* reveals fullness or prominence of the precordium with a distinct impulse. *Palpation* detects the impulse one or two intercostal spaces lower down and to the left. It is stronger and more or less diffused—the heaving impulse. *Percussion* determines an increase in the area of cardiac dullness vertically and transversely on the left side of the sternum, unless the right ventricle is also hypertrophied, when the cardiac dullness is increased to the right of the sternum. *Auscultation* in simple hypertrophy without any valvular changes detects a loud first sound of a somewhat metallic quality, the second sound being strongly accentuated. In the presence of valvular disease the characteristic murmurs are heard in addition."—(Hughes' *Practice of Medicine.*)

Cardiac Dilatation: "*Inspection* detects enlargement and distention of the superficial veins and an indistinct, often wavy and diffused, cardiac impulse. If tricuspid regurgitation is present jugular pulsation will be observed. *Palpation* confirms inspection; the impulse is feeble, irregular, and heaving. *Percussion* serves to determine extension of the area of cardiac dullness transversely and especially toward the right side. *Auscultation* in the presence of valvular lesions reveals characteristic murmurs. If there are no valvular lesions the cardiac sounds are weaker than normal and the first sound is sharper in quality than usual."—(Hughes' *Practice of Medicine.*)

A *hemic murmur* is a murmur usually systolic, soft, and blowing, heard best over the pulmonic area, associated with evidences of chlorosis or anemia, and affected by the position of the patient, and denotes as a rule an impoverished condition of the blood.

2. Aneurysm of the Thocacic Aorta. "Any part of the thoracic aorta may be affected, and the symptoms arising therefrom are very variable. The fusiform type is most commonly met with in the early stages, a limited sacculation often supervening as the disease advances. (1) In the *ascending part of the arch* the swelling rarely reaches a great size, especially if it is intrapericardial, the sac usually rupturing before marked pressure signs are evident.

"(2) When arising from the *transverse part of the arch*, the symptoms vary with the direction taken by the enlargement. If it projects *upward*, a pulsating tumor may appear at the episternal notch, and cerebral effects may then ensue from interference with the circulation through the carotids, or from pressure on the venous trunks. If it extends *anteriorly*, it may form a large tumor with comparatively slight pressure effects, except the pain arising from its erosion of the thoracic wall; it then appears as a pulsating swelling to the right of the sternum. If the enlargement takes place either *posteriorly* or *downwards* within the concavity of the arch, symptoms in the shape of dyspnœa and dysphagia are early produced from the close contiguity of the trachea, œsophagus, and pul-

monary vessels. Dyspnœa may also be due to pressure upon the left recurrent laryngeal nerve, causing paresis to the cricoarytenoideus posticus muscle and difficulty in opening the glottis; the voice, moreover, becomes harsh and the cough hard, with what has been described as a 'metallic ring' about it, which is extremely characteristic. Laryngeal or tracheal stridor may be noticed in these cases, and a dragging of the trachea synchronous with the heart's action (the so-called 'tracheal tug'). Radiographic examination is a valuable means of diagnosis.

"(3) Aneurisms of the *descending arch* and *thoracic aorta* often attain considerable dimensions, and may project posteriorly to the left of the vertebral column, causing a pulsating swelling. The only prominent symptoms are pain, due to erosion of ribs or vertebræ, and interference with deglutition, which may be so great as to suggest the presence of an œsophageal constriction; in fact, before a bougie is passed in any case of dysphagia it is always advisable to make certain by radiography that an aneurism is not present. Ausculation in the left vertebral groove may also reveal the existence of a systolic bruit where such a condition exists."—(Rose and Carless' *Surgery.*)

3. The *methods of physical diagnosis* are: Inspection, palpation, percussion, and auscultation.

"The technique of inspection is as follows: (1) The patient should be stripped of clothing as far as possible. In children and in the male adult all clothing should be removed from the chest except that which may be necessary to avoid chilling of the surface; in the female, delicacy may demand that the patient be thinly covered, but wherever it is required the examiner should not hesitate to demand that the surface be bare, if only a part at a time, so that correct observations may be made. Where for any reason it is impossible to bare the chest thoroughly, much of the observation that would ordinarily be made by inspection must be made by palpation. (2) Inspection may be made with the patient either standing, sitting or in the recumbent posture, according to the circumstances of the case. When the patient is able, the standing or sitting posture is preferable, inasmuch as it is easier for the observer, and the movements of the chest are not interfered with. The patient should assume a natural or customary posture. Usually as soon as inspection is commenced they try to assume a "correct" posture. (3) It is necessary that the light fall equally on both sides, as the value of inspection is in the comparison of one portion of the chest with the corresponding portion of the opposite side. The observer generally stands directly opposite the patient, so as to have both sides within the range of vision. Where it is necessary to determine slight variations in the upper portion of the thorax, it can often be best done by the observer standing behind the patient and looking over the shoulder and downward along the clavicle and upper ribs. This will show the slightest degree of depression in these areas."—(Le Fevre's *Physical Diagnosis.*)

Technique of Palpation: "In order to obtain the most satisfactory results from palpation, it is necessary that the patient assume an easy position, whether it be standing, sitting or reclining. When feasible, the patient should be examined in more than one position, as posture has a marked influence on the position and force of the cardiac impulse. The observer should place his hand lightly over the lower portion of the præcordia and note the general character of the sensation conveyed to it. Then, by the tips of the fingers, the exact location of the maximum apex beat may be determined. Frequently, when the pulsations are indistinct or diffuse, it is difficult to locate exactly the point of maximum intensity of the apex beat. In such cases it is best to apply the tips of the fingers to the thorax beyond the point of visible pulsation, and, moving them along the interspaces, locate the point at which the elevating impulse is felt most distinctly.

Palpation enlarges the knowledge obtained by inspection of increase in size of the præcordia by determining whether or not the enlargement is due to œdema, inflammatory swelling, or new growths of the soft parts. In regard to the bony thorax, it determines the degree to which it is influenced by each cardiac beat. . . . To palpate the anterior surface of the chest, the examiner stands behind the patient and places the hands over the chest so that the fingers are parallel with the ribs, resting in the intercostal spaces. By these means a better perception of motion and of time is obtained. To palpate the posterior surface, the position is reversed. The antero-posterior movement of the chest is noted by placing one hand over the sternum in front, and the other posteriorly over the spine. The movement of the clavicle and upper ribs is observed by placing the hand over the shoulder, the fingers resting on the anterior portion of the chest, and the thumb behind on either side of the spine."—(Le Fevre's *Physical Diagnosis.*)

Technique of percussion: "This physical method of diagnosis is employed by striking the chest gently with finger-tips, or by means of a percussion hammer (plexor) with a piece of ivory (pleximeter) interposed. The patient is preferably examined in the standing position. *Immediate percussion* is performed by simply striking the chest wthout an interposing substance. *Mediate percussion* is performed when the finger or pleximeter is interposed. The stroke is made by the middle finger or by the index- and middle fingers combined. The interposing finger or pleximeter must be pressed down firmly on the surface so as to yield a clear note. The method should be employed systematically on the two sides of the chest in corresponding location without moving promiscuously from one to the other position."—(Gould and Pyle's *Cyclopedia of Medicine and Surgery.*)

Technique of auscultation: "To auscultate satisfactorily, attention should be given to the position of the patient. Both sides of the chest should have opportunity to move with equal freedom. The patient should breathe naturally, and care should be taken that inspiration and expiration are not noisy. It is impossible for many persons to breathe naturally when their attention is called to the act. Usually the inspiration is taken quickly and forcibly; the breath is held for an appreciable time and then either forced out rapidly or allowed to escape so slowly that no sound is heard. In nervous patients fairly natural breathing may be obtained after coughing, or by having the patient first talk for a certain time. All constricting clothing, as stays, etc., should be removed, so that the chest may be as nearly normal as possible. As the value of auscultation is comparative, symmetrical points on the two sides should be examined and the differences noted."—(Le Fevre's *Physical Diagnosis.*)

4. *General retraction of the abdomen.* "The abdomen as a whole may be sunken in wasting diseases. It is very marked in inanition from stricture of the esophagus or pyloric stenosis and gastric dilatation; in the violent vomiting and purging of cholera and severe gastro-enteritis; and in the pernicious vomiting of pregnancy. If tenderness and muscular rigidity is associated with the retraction, one may suspect the early stage of peritonitis. The scaphoid (boat-shaped) abdomen is also seen as a symptom of meningitis (basal especially), tumor of the brain, and lead colic, because of the irritative tonic spasm of the abdominal muscles."—(Butler's *Diagnostics of Internal Medicine.*)

5. *General causes of distention of the abdomen:* Fat in the abdominal walls; fluid in the peritoneal cavity; gas in the stomach and intestines; an abdominal tumor; pregnancy.

6. *Technique of splenic examination: Inspection* is rarely of service. *Palpation:* The patient should be in the recumbent position. Then lay the warm hand flat upon the abdomen so that the finger tips, by exerting pressure and pushing up a fold of skin, lie close to and under the left costal margin at the tenth cartilage. The edge of the spleen, if sufficiently enlarged, may then be felt without further trouble. If not, desire the patient to draw several deep breaths, when the sharp splenic edge, moving with respiration, will be perceived to slip or ride over the ends of the fingers. Still further aid may be obtained by placing the unoccupied hand posteriorly between the ends of the tenth and eleventh ribs and making firm pressure so as to tilt the organ forward and make it more accessible. *Percussion:* The patient may be sitting or standing, or if recumbent should lie partly turned to the right, *i. e.* midway between the dorsal and right lateral postures—in either case with the left arm over the head. The per-

cussion strokes should be light, except in percussing the posterior portion of the spleen where its dullness merges into that of the left kidney. *Auscultation:* A friction sound may be heard over the spleen if its peritoneal investment is inflamed, as in infarcts due to a septic embolism or thrombus, or in the splenic abscess following such infarctions."—(From Butler's *Diagnostics of Internal Medicine.*)

7. The *leucocytes are increased* in: Inflammatory diseases, abscesses, certain infectious diseases (such as erysipelas, pneumonia, meningitis, diphtheria), lymphatic leucemia, splenomedullary leucemia.

Leucopenia is found in: Pernicious anemia, typhoid, and miliary tuberculosis.

8. DIAGNOSIS OF PARESIS: The development of the following symptoms removes all difficulties in diagnosis: *Mental*—alteration in character, loss of memory, defective will-power, changed moral sense, insomnia, violent impulses, melancholia or mania, unsystematized delusions of expansive character, with an exalted sense of well-being, gradually ending in dementia. *Physical*—hesitating, slurring speech, tremor of the lips, tongue, and upper extremities; pupillary changes, mysosis, loss of light reaction; exaggerated wrist-, elbow-, and knee-jerk; attacks of syncope, vertigo, epileptiform seizures, ataxia, trophic changes, and finally paralysis."—(Hughes' *Practice of Medicine.*)

DIAGNOSIS OF LOCOMOTOR ATAXIA: "There are four pathognomonic symptoms of locomotor ataxia, the presence of which makes the diagnosis positive; they are Westphal's symptom—absence of patellar reflex; Romberg's symptom—swaying of body and inability to maintain erect position with closed eyes; the Argyll-Robertson symptom—loss of pupil reflex to light, but reaction to accommodation retained; Fränkel's symptom—hypotonia."—(Hughes' *Practice of Medicine.*)

9. The *most common valvular heart disease* is mitral regurgitation. The *most dangerous valvular heart disease* is aortic regurgitation.

"THE PHYSICAL SIGNS OF THE LOSS OF COMPENSATION are of two classes:

"I. DIRECT SIGNS OF TRICUSPID REGURGITATION:—(1) Systolic murmur in the tricuspid area. (2) Weakness of the second pulmonic sound (part of the blood which should flow into the pulmonary artery regurgitating into the right auricle. (3) Marked irregularity of the pulse. (4) Venous pulse, best seen in the neck (there being no valves between the jugulars and the incompetent tricuspid valve), and also in the liver (hepatic pulse).

"II. SIGNS OF PASSIVE CONGESTION. (1) Edema, beginning where the circulation is normally at the greatest disadvantage, *i.e.* in the feet and ankles, and extending gradually upwards till the trunk and arms may be affected. (2) In grave cases ascites, hydrothorax, hydropericardium. (3) Congestion of internal organs:—(*a*) *Liver.* Enlargement, tenderness, slight icteric tinge. (*b*) *Kidneys.* Scanty, high-colored urine, abundant urates, albumin in varying amount, a few hyaline casts and isolated red blood corpuscles. Urea not diminished. (*c*) *Stomach.* Dyspepsia, catarrh, often hematemesis. (*d*) *Lungs.* Signs of congestion and edema; fine, moist râles and dullness at the bases."—(Wheeler and Jack's *Handbook of Medicine.*)

10. TUMORS OF THE BRAIN:—"The Symptoms are (1) Those due to increased intracranial pressure, such as fixed *headache*, giddiness, loss of memory, epilepsy, and stuper ending in coma. Tenderness on pressure may mark the site of the tumor. (2) *Vomiting*, not preceded by nausea, and bearing no relation to the taking of food. The temperature is often subnormal. (3) *Optic neuritis* is generally present. The edges of the disc are blurred, the vessels are tortuous and seen irregularly, and atrophy follows if life is prolonged. (4) *Focal symptoms* are produced when an area of the brain with definite functions is involved, and are at first irritative, followed by paralysis."—(*Aids to Surgery.*)

11. *Neuritis.* "The symptoms of neuritis will necessarily vary much according to the functions with which the affected nerve is concerned. There may be impairment of special or common sensibility, or paln may exist (referred to the peripheral distribution of the nerve), with more or less distinct tenderness along its course or at its point of emergence from some bony canal. In these cases the pain is generally paroxysmal and neuralgic in character, while the skin is hyperesthetic, and perhaps shows some vasomotor or trophic changes. Where a strictly motor nerve is implicated there may be twitchings of the muscles to which it is distributed, followed by more or less distinct paralysis, and subsequently marked wasting of the affected muscles. In the case of a mixed nerve being involved, both kinds of symptoms present themselves—that is, more or less severe pains and tenderness, with trophic symptoms, and distinct paresis or paralysis, with subsequent atrophy of the muscles to which the nerve is distributed."—(Quain's *Dictionary of Medicine.*)

12. *Physical signs of lobar pneumonia: "Inspection* reveals during the first stage deficient movement of the affected side, due to pain. The apex-beat is normal in situation, and the interspaces do not bulge. In the second stage the healthy side rises normally, the affected side lagging behind. If both lower lobes are impervious to air, the diaphragm cannot descend and the epigastrium does not project during inspiration, the breathing being conducted by the upper part of the chest (superior costal respiration). *Palpation* during the first stage shows the vocal fremitus to be more distinct than normal, especially over the diseased portions. In the second stage, the vocal fremitus is markedly exaggerated, except in those rare instances of occlusion of the bronchi by secretion. The cardiac impulse is felt in the normal position. *Percussion*—In the first stage, the percussion note is slightly impaired at times, having a hollow or tympanitic quality. In the second stage there is dullness over the affected parts, with an increased sense of resistance. Over unaffected adjoining area the resonance is increased (Skoda's resonance). *Auscultation.*—In the first stage there is heard over the affected part a feeble vesicular murmur, associated with the true vesicular or crepitant (crackling) râle, heard at the end of inspiration only. In the second stage there is harsh, high-pitched, bronchial respiration, at times resembling a to-and-fro metallic sound, except in those rare instances in which the bronchi are more or less filled with secretion. Bronchophony, or distinctly transmitted voice, is present and at times pectoriloquy, or distinct transmission of articulated sounds, may be heard. In the third stage, the breathing changes from bronchial to bronchovesicular and the crepitant râle (crepitatio redux) returns. As resolution proceeds, the breath sounds are associated with large and small moist and bubbling râles."(Hughes' *Practice of Medicine.*)

(*To be continued.*)

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

PATHOLOGISCHE PHYSIOLOGIE. B. H. E. HERING. 120 pages. Published by Georg Thieme.

PROCEEDINGS OF THE MEDICAL ASSOCIATION OF THE ISTHMIAN CANAL ZONE. 118 pages with illustrations. Published by the Health Department, the Panama Canal Zone.

THE MEDICAL CLINICS OF NORTH AMERICA, September, 1921, Vol. 5, No. 2. 592 pages with illustrations. Price, $12 per year. Published by W. B. Saunders Company

A FORM OF RECORD FOR HOSPITAL SOCIAL WORK. By GERTRUDE L. FARMER. 81 pages. Price, $1.50. Published by J. B. Lippincott Company, Philadelphia.

ANNUAL REPORT OF THE SURGEON GENERAL, U. S. NAVY, FOR 1921. 156 pages with tables. Published by the Government Printing Office, Washington.

REPORT OF THE U. S. INTERDEPARTMENTAL SOCIAL HYGIENE BOARD, year ending June, 1921. 198 pages with tables. Published by the Government Printing Office, Washington, D. C.

Medical History.

NEW BOOKS AND OLD.

XXI. GARRISON'S HISTORY OF MEDICINE.

By JOHN RUHRÄH, M.D.,

BALTIMORE, MD.

If I were to start a medical library for a medical student, practitioner, hospital, or some medical society the first book I would buy would be the Third Edition of Garrison's "History of Medicine." There are several reasons for this. One is that I am a firm believer in the historical method of approach—what man has done and thought in the past are important in understanding the present and in foretelling the future. Much of the present day thought that seems inexplicable becomes clear when viewed in its historical perspective. There is too great a tendency, especially in this country, to suppose that modern medicine sprang into existence overnight much in the manner that Pallas Athene sprang full-panoplied from the head of Zeus. Such is not the case. The flower of modern medicine is the result of much watering, and, if I may be permitted the expression, of much manuring in the past; the real fruition, the real harvest will come in some far distant future. It is our duty to tend the plant which has been handed down to us from the ages and to pass it on to those who come after, let us trust, better from our care. Strange gardeners have contributed to its raising, stranger still now minister to it, prune it, graft it, fertilize it, protect it, and expose it. It is a hardy plant. It survives all sorts of mistakes; branches that were once supposed to be the strongest wither away and drop off, while tender shoots scarce noticed, come to be regarded as of the greatest importance.

Medical history, or any other kind for that matter, may be likened to a play, with its changing scenes, its various actors. It is one of those continuous performance plays with an ever-changing audience. To understand the play, one must be familiar with what has gone before. Garrison's book serves us well in this respect. He has drawn a vivid picture of what has happened with an account of the principal actors. Starting in at the beginning of history he points out the identity of all forms of ancient and primitive medicine. Just as all primitive religions are built along the same lines, so all primitive medicines follow the same plan—and ancient medicine was primitive medicine. From the ancients the story turns to the Egyptians, who have furnished the human race with so many basic ideas, and from them to Sumerian and Oriental medicine. Then the scene shifts to Greece, the wonderful Greece of old, to the days of Hippocrates and his school, and almost before we know it the Græco-Roman period is ushered in with Galen as its outstanding figure. The authority of this old worthy was such that for a thousand years or more the medical world of Western Europe stood still. What there was of progress was made by the Byzantine scholars, but they were rather encyclopedists than investigators. A few hundred years and the leaders of medical thought are to be found among the Mohammedans and the Jews. Then comes one of the most fascinating periods, the medieval, the complete story of which is yet to be written. In this third edition Garrison has added considerably to this chapter giving the newer researches of such scholars and authorities as Sudhoff, Neuburger, Wickersheimer, and Singer. From the mystery of the middle ages medicine emerges with new life, and reformation came alike to church and science, indeed a period of new birth. The next four sections deal with the subject of medicine in the past four centuries. These Garrison has aptly characterized as the age of scientific endeavor (17th); the age of theories and systems (18th); the beginning of organized advancement of science (19th); the beginning of organized preventive medicine (20th). All this takes three-quarters of the volume, a running, readable narrative, with a wealth of names and records of accomplishment. Never before in the history of medicine has so much been crowded into such small space and been made withal so clear, so charming, so instructive, without the curse of tedium. The very wealth of material dazzles one, but Garrison maintains a balance throughout. The only other book I call to mind that approaches it in this manner is Pagel's "Geschichte der Medizin," as revised by Sudhoff, where one gets somewhat the same readable narrative.

Old James Atkinson, of York, author of "Medical Bibliography A. B.," a remarkable work in more ways than one, says in his preface, "There is not perhaps any man so good a judge of the difficulty of writing a book, as an actual author." This is particularly true of Garrison's work, for I am sure unless a man has endured the throes of literary parturition he can never understand the labor pains that it must have taken to bring forth such a remarkable presentation of so complicated and difficult a subject. Perhaps instead of labor pains I had been more correct had I used the expression painful labor. To handle such a mass of names, dates, citations, quotations, a man requires patience which I doubt would have been found in Job himself had printing then been invented. When it comes to the exposition of the subject in such a clear, orderly, understandable way, it requires nothing short of genius. There has never been in America, and there probably will not be again for a long while, anyone possessing the immense store of knowledge of all that pertains to medical history and bibliography as has Garrison. Aided by a memory of uncanny kind, by industry unceasing, and by natural aptitude, he has acquired not only an enormous number of facts, but also an understanding which he is fortunately able to impart to others.

At the beginning of this article I said this history would be the first book chosen for a medical library. A second reason for this is the wealth of bibliographic material which it contains. Nowhere can one find so much within so few pages. Of course there are many references throughout the text made available through the index of names and subjects. The index of personal names alone covers twenty-five pages and contains about four thousand items; where biographical material is given the references are distinguished by bold type. The special material is added in the form of appendices. The first is a medical chronology starting with the neolithic age and ending 1920. This idea of a chronological table is an old one and, since the

printing of the elaborate one in Kurt Sprengel's "History of Medicine," has been much used. Garrison has had, of course, the benefit of the work of previous authors, and so has given a more compact table than many of his predecessors. It seems a pity he did not include some such arrangement as is found in the "Zeittafeln zur Geschichte der Medizin" of J. L. Pagel, where the concurrent happenings in various parts of the world and in the different departments of medicine are shown, but even Pagel published them in a separate volume. They are most useful for a beginner.

The second appendix is entitled "Hints on the Study of Medical History," and this is prefaced with a quotation from Abel's Mellin lecture, 1915, to wit: "Greater even than the greatest discovery is to keep open the way to future discoveries." Garrison is a believer in the method used by James Finlayson of Glasgow, who found that the didactic lecture on the subject was less useful than a "clinic" in a medical library, where instead of hearing of Hippocrates or Galen, the student saw and handled the actual books of these and other old worthies. This idea has been used by Billings, Osler, Welch, Dock, and others. Garrison, like Finlayson, is a believer in small classes where all present may take part, a method used by Trousseau in teaching medicine in the wards, which recalls that Sylvester once lectured on higher mathematics to a class of one. Osler taught many of his students history of medicine at his own home; others prefer to mix it liberally in the class room, laboratory, or clinic. Perhaps the method most used in this country is the medical history club or society of which there are quite a number.

The third appendix deals with collateral reading and contains a fine two-page estimate of the works of other medical historians, giving high praise to Bass's "Grundriss." There are really not so many medical historians of note, Le Clerc (1696), Freind (1725-27), Schulze (1728), Haller (1751), and Blumenbach (1786), broke the ground, and then Kurt Sprengel (1792-1803) published his seven-volume work dealing with the medicine of the ancients, an extraordinarily fine piece of accurate workmanship. Hecker (1822-29), Bostock (1834), Puccinotti (1850-56), Meryon (1861), Daremberg (1870), come and go and Heinrich Haeser (3rd edition, 1875-82), is here with a monumental history. Bass, Puschmann, Pagel, Sudhoff, Neuburger, Withington, and Garrison represent the best of the modern period.

The second part of the third appendix is an invaluable list of biographical references. First mention is made of the usual sources of medical biography, the works of Éloy, Bayle and Thillaye, Jourdain, Hirsch, Pagel, Thatcher, Gross, Kelly, not forgetting the numerous articles about medical men in the National Dictionary of Biography. There follows an alphabetical list from Acland to Zimmerman, each name with several references so that the labor of consulting three consecutive series of the Index Catalogue, forty volumes in all, is avoided. Perhaps of even greater value is the list of histories of special subjects which follows. This covers some fourteen pages and is remarkably full. Alchemy, anatomy, surgery, the specialties and allied subjects, the medicine of various lands and peoples, epigraphy, fees, folk-lore, to mention but a few of the captions. As I said once before in these columns, Garrison has done for medicine what Baedecker did for Europe and has done it with infinite charm.

Of the body of the work it is difficult to speak without seeming to praise too much. A quotation or two will give a better idea of the style and character of the book than pages of description. Take for example the page on the doctor in literature:

As modern physicians have been abundantly caricatured in the graphic arts, so the business-like tendencies of the profession in our own time have afforded liberal opportunities for literary satire. Bass has hit off the early nineteenth century doctors of this type as characterized "by the fashionable cut of their clothing, amiability, and the thermometer, stethoscope, percussion hammer, etc., peeping out of their coat pockets." All this implies a somewhat sweeping survey of a whole period, but we find similar traits of smartness in such characters as Dickens' Dr. Slammer in "Pickwick" or Dr. Jobling in "Martin Chuzzlewit," and Charles Reade's Dr. Aberford in "Christie Johnstone." Thackeray's Dr. Firmin and Wilkie Collins' Dr. Downward represent types of a craftier and more dubious kind. The best imaginative portrait of the high-bred physician of intellectual type is that of Lydgate, in George Eliot's "Middlemarch," a novel which, on the whole, affords the most effective sidelight on English medicine in the late Georgian and early Victorian periods. The keenest edge of the author's satire is reached in the medical gossip of the gentlewomen in the tenth chapter. Mrs. Cadwallader likens Casaubon, the fossil bridegroom of the beautiful Dorothea, to a dose of medicine, "nasty to take and sure to disagree"; and Lady Chettam, in discussing Lydgate's superior family connections, observes:

"One does not expect it in a practitioner of that kind. For my own part, I like a medical man more on a footing with my servants; they are often all the cleverer. I assure you I found poor Hick's judgment unfailing; I never knew him wrong. He was coarse and butcherlike, but he knew my constitution."

The same note is sounded in Major Pendennis' horror lest a lady marry her uncle's doctor, which would seem a far cry from the present esteem in which physicians are held. Henry James' "Washington Square" (1880) opens with an amusing assurance of their superior status in the United States. Balzac immortalized the French country doctor; no less than Dupuytren was the original of his Desplein, but his Horace Dianchon is a fancy portrait. Gustave Flaubert, Samuel Warren, Charles Lever, Oliver Wendell Holmes, Weir Mitchell have all approached the subject from different angles. Mitchell has made a clever study of a quack. The medical students of Dickens, Albert Smith, and others are sufficiently well known. Turgenieff's Bazaroff, the agnostic, anarchistic student of Eastern European type, is a genuine creation.

Another page taken at random deals with the prophylaxis of puerperal fever:

"The greatest single achievement of the New Vienna School was the determination of the true cause and prophylaxis of puerperal fever. In the eighteenth century, Charles White of Manchester, England, had enlarged upon the advantages of scrupulous cleanliness in these cases, and on February 13, 1843, Oliver Wendell Holmes (1809-94) read to the Boston Society for Medical Improvement his paper 'On the Contagiousness of Puerperal Fever,' in which he announced that women in childbed should never be attended by physicians who have been conducting post-mortem sections or cases of puerperal fever; that the latter disease may be conveyed in this manner from patient to patient, even from a case of erysipelas; and that washing the hands in calcium chloride and changing the clothes after leaving a puerperal fever case was held to be a preventive measure. Holmes' essay stirred up violent opposition

on the part of the Philadelphia obstetricians, Hodge and Meigs, and, in 1855, he returned to the charge in his monograph on 'Puerperal Fever as a Private Pestilence,' in which he reiterated his views and stated that one 'Senderein' had lessened the mortality of puerperal fever by disinfecting the hands with chloride of lime and the nailbrush. This 'Senderein' was Ignaz Phillip Semmelweis (1818-65), a Hungarian pupil of Skoda's and Rokitansky's, who, in 1846, had become an assistant in the first obstetric ward of the Allgemeines Krankenhaus in Vienna. This ward had acquired such a high mortality in puerperal cases that women begged in tears not to be taken into it. Semmelweis had noticed that the first ward differed from the second (which had a lower mortality rate) in that students came into it directly from the dissecting room for instruction, often making vaginal examinations with unclean hands, while in the second ward, devoted to the instruction of midwives, much greater attention was paid to personal cleanliness. With this idea in mind, he also made a careful study of the autopsies in the fatal puerperal cases. In 1847, Kolletschka, Rokitansky's assistant, died of a dissection wound, and Semmelweis was present at the post mortem. As he stood beside the body of his former instructor, he noticed that the pathological appearances were the same as in the unfortunate puerperæ of the first ward, and he now had his chain of evidence complete. He immediately instituted such precautions in the handling of labor cases that the mortality curve sank from 9.92 to 3.8 per cent. In the following year he had a mortality as low as 1.27 per cent., and all through the simple expedient of washing the hands in a calcium chloride solution in connection with pregnancy and the conduct of labor. Semmelweis is thus the true pioneer of antisepsis in obstetrics, and while Holmes antedated him in some details by five years, the superiority of his work over that of his predecessor lies not only in the stiff fight he put up for his ideas, but in the all-important fact that he recognized puerperal fever as a blood poisoning or septicemia (1847-49). Like Holmes, he met with fierce opposition, and while Rokitansky, Hebra, Michaelis, and, to his lasting honor, Skoda stood by him, he was persecuted by Scanzoni, Carl Braun, and the orthodox obstetricians of the day. Disgusted, he suddenly left Vienna for Budapest, where he became in due course professor of obstetrics at the University (1855) and published his immortal treatise on 'The Cause, Concept, and Prophylaxis of Puerperal Fever' (1861), as well as his scathing 'Open Letters to Sundry Professors of Obstetrics' (1861). But his sensitive nature was not equal to the strain of violent controversy, and brooding over his wrongs brought on insanity and death. He is one of medicine's martyrs and, in the future, will be one of its far-shining names, for every child-bearing woman owes something to him."

My impression is that Garrison has produced a book which will for many a day be used as an authoritative work of reference. I hope the publishers have printed a number of copies on paper that will withstand the ravages of time so that readers a few hundred years from now may have some idea of our ideas on the subject of medical history and may enjoy this captivating narrative.

One should also bear in mind Garrison's other works, the large number of separate articles printed in various journals and his introductions to such works as the Frank edition of Choulant, and Packard's edition of the "Regimen Sanitatis Salernitanum." Three other remarkable pieces of work are now in progress. One is one volume of the medical history of the late war; of this book I know nothing whatever, but it undoubtedly will appear in due time; the second, which I have had the pleasure of reading in manuscript, is a remarkable history of pediatrics now being printed in the system of pediatrics in preparation under the editorship of Dr. Isaac A. Abt of Chicago; another is the history of the endocrine doctrine, a valuable and exceedingly timely piece of work; and lastly, some notes on the history of military medicine.

Crabbe on Doctors.—Although Crabbe, the poet, has partially emerged from the obscurity that invested his name and works for many years after his death, he is still far from receiving the attention he deserves from the medical profession of which he was once a member. He had a good old-fashioned medical education. Errand boy for a time to Mr. Page, surgeon, of Woodbridge, his father later on sent him up to London "to pick up a little surgical knowledge," *à la* Roderick Random, and on his return to his native town, Aldeburgh, he became assistant to a surgeon there. When his master departed this life Crabbe set up for himself, but does not appear to have been very successful in practice, no doubt because he was too much of a scribbler. He subsequently shook the dust from his sandals on Aldeburgh and returned to London, where he managed to publish a volume of his poems. These did not bring him in much money, but attracted the attention of Burke, with whose help he became chaplain to the Duke of Rutland, and finally settled down as a country parson. By that time, however, Crabbe had become very familiar with the conditions of a country doctor's life, a familiarity which transpires in hie poetry. Theirs the duty:

> To ease the victim no device can save
> And smooth the stormy passage to the grave.

He waxes very sarcastic about the young physician who seeks to make his reputation by the writing of books:

> With them the treatise is a bait that draws
> Approving voices—'tis to gain applause
> And to exalt them in the public view,
> More than a life of worthy toil would do.

And he adds that "It weighs not much on what their powers be shown, When all his purpose is to make them known." But Crabbe, after all, handles doctors in a kindly spirit. He had learned to appreciate the abnegation and devotion of duty of "these men of serious words and sober style," friends "with whom we seldom smile,'" whose devotion he asserts "springs from nobler motives than a fee." But when he turns to the subject of the quack he lashes himself into a fury—and would do so once again if he lived in our times, for conditions in this respect have not materially changed. He deplores:

> That creatures Nature meant to clean our streets,
> Have purchased lands and mansions, parks and seats.

with "Twenty names of cobblers turned to squires," whose testimonials bolster up the quack's claims to have cured:

> Men snatched from graves as they were dropping in,
> Their lungs coughed up, their bones pierced through their skin;
> Their liver all one scirrhus and the frame
> Poisoned with evils which they dare not name.

And these, after taking the nostrum, "are now as roaches sound and all as brisk as bees." Crabbe's descriptions of village life in its various aspects are entertaining reading, especially so to country doctors, to whose benevolent notice we commend the lucubrations of their one-time confrère.—*The Medical Press.*

SOME CONSIDERATIONS OF THE PHARMACOLOGY AND THERAPEUTIC VALUE OF ALCOHOL.*

BY GEORGE B. WALLACE, M.D.,

NEW YORK.

So many conflicting statements of the effects of alcohol have been made, so much variation in experimental conditions has existed, and so much in the way of experiment and observation has started with the intention of proving the correctness of preconceived ideas, that it is a difficult matter to assemble, interpret, and evaluate the essential facts which have been obtained. The history of the use of the drug is one of tides of favor and disfavor. Just now the tide is low, with active efforts being made to erect such barriers as will prevent it from again flowing in. If it can be shown that alcohol is a curse and in no sense a blessing, these efforts to abolish its use may well be successful. If, on the other hand, it can be established that alcohol is of value, human effort is not likely to permanently prevent its legitimate employment. The present day discussion seems to center in whether alcohol has any therapeutic action of value, and I shall endeavor to limit myself to a consideration of this main point.

It is obviously out of the question for me to cover the entire pharmacological field concerning alcohol, and I have selected only three phases of the subject, namely the effect on the alimentary tract, the effect on nutrition, and the effect on the circulation. What conclusions I may draw in these connections will have to do only with effects of therapeutic doses.

In a consideration of the action of alcohol on the alimentary tract, there are, broadly speaking, two questions especially that present themselves: These are the effect on appetite and the effect on digestion. It is understood, of course, that appetite is quite distinct from hunger.

There are so many factors involved in the sensation, appetite, that it is a difficult matter to establish its relation to any single factor. Convincing experiments along this line are lacking. As a matter of fact it hardly seems necessary to rely on experiment to determine the effect of alcohol on appetite. It is a matter of common knowledge and experience that in some individuals it promotes appetite, and that in others it has the opposite effect. That we are unable to explain this difference in action or define the conditions which make possible a favorable effect, is regretable, but does not invalidate the fact that alcohol may act as a decided stimulus to appetite.

When we consider the action of alcohol on gastric secretion and digestion, we find a great mass of experimental data. In the carefully planned and executed experiments of Chittenden, Mendel, and Jackson,[1] it was shown that alcohol and alcoholic drinks had a marked effect on the empty stomach in dogs, increasing very greatly the flow of gastric juice and the content of acid and solids. The gastric juice was also strongly proteolytic. In another series of experiments, the effect on gastric digestion was studied, a dog with a gastric fistula being the subject. Meat was given as food, the alcohol being introduced through the fistula. At intervals small quantities of gastric contents were withdrawn through the fistula and examined, the amount of undissolved meat being taken as a measurement of the digestion. The alcohol and control experiments showed no particular differences, and the conclusion was drawn that alcohol does not materially affect the rate of digestion.

In experiments of a similar nature carried out in man it has been shown generally that alcohol excites gastric secretion in an empty stomach, although with this there may be a phase of inhibition. With regard to digestion, a number of observers state that there is a retardation, others have found no alteration and still others an acceleration. Possibly its action varies with the individual, as in the case of appetite. It is evident that further knowledge is required here. It may be pointed out, however, that Zuntz and Magnus-Levy,[2] in a series of metabolic experiments, found that alcohol did not lessen the utilization of food by the body and that Atwater and Benedict[3] believe that the utilization is actually increased.

Krehl[4] states that the gastric juice is diminished in acute infections and it would be of great interest to know what action alcohol would have here. Our zeal for knowledge would hardly justify, however, the necessary experiments in such cases.

I may summarize this part of the subject as follows: Alcohol, in proper dosage, is a definite stimulus to appetite in many individuals. There is no satisfactory evidence that it improves digestion, or, on the other hand, that it affects it unfavorably.

The nutritive value of alcohol is a subject which in the past has led to much controversy. A series of experiments remarkable for the high degree of patience and thoroughness shown, was finally carried through by several observers, with striking uniformity of results, and at the present time there

*Read before the Philadelphia County Medical Society, December 14, 1921.

seems to be complete agreement on the subject. It is not necessary to quote more than one set of experiments in this connection and those of Atwater and Benedict[5] have been selected. The experiments consisted in a study of metabolism, by means of the respiration calorimeter, on three different men. They were carried on through a number of days, periods off from four to nine successive days being spent in the calorimeter. During one period the ordinary diet was given, during another, alcohol was added to the diet. The alcohol amounted to about 72 g. a day. It was given as pure alcohol or as whisky or brandy, mixed with coffee or water, and the total daily amount was divided into six doses. The daily quantity of alcohol corresponded to that contained in a bottle of claret, or six ounces of whisky or five ounces of brandy. It was capable of supplying about 500 calories of energy. The points brought out in this work are as follows:

1. With this quantity of alcohol taken daily, not more than 2 per cent. was given off from the body unoxidized; that is, the coefficient of availability is 98 per cent.

2. The alimentary digestion of food, that is the amount of food digested and absorbed, was not interfered with. In fact the effect of alcohol seems to be to slightly increase the availability of the nutrients of the diet, especially of the protein.

3. There was no appreciable increase in loss of heat by the body when this quantity of alcohol was added to the diet.

4. The potential energy of the alcohol oxidized was transformed completely into kinetic energy, either as heat, or as muscular work, or both.

5. The efficiency of alcohol in protecting body fat was proven. Alcohol can replace isodynamic amounts of fat and carbohydrates.

6. The efficiency of alcohol in protecting body protein was evident, but was not fully equal in this respect to the isodynamic amounts of the ordinary nutrients. In individuals not accustomed to alcohol, a period of three days or more is required before the full protein protective action of alcohol develops.

These conclusions, in connection with the fact that alcohol requires no digestion to make it available, and that it is easily and quickly absorbed from the alimentary tract, seem to warrant the assumption that it has a definite value as a source of body energy. But before this assumption can be accepted as true there is another point to be settled, that is whether alcohol has any injurious effects, either on metabolism, on in other directions, which might nullify its usefulness as a food.

Some years ago Beebe[6] reported some experiments on himself in which the effects of alcohol on uric acid metabolism were studied. He drew the conclusion that alcohol, in what he considered a moderate amount, causes an increase in the excretion of exogenous uric acid, and believed that this is due to a toxic action of the liver. This work has been carefully repeated by Mendel and Hildreth,[6] giving alcohol in the dose and manner employed by Atwater and Benedict. They find in agreement with Beebe that the uric acid output is increased, and while they are unable to explain this increase, they believe it points to a toxic action on metabolism. It may be added that their work showed that the nitrogenous partition was unaffected except with regard to uric acid.

Hunt[7] has also offered evidence of a possible harmful effect on metabolism. He has shown that mice treated with small doses of alcohol for some time, acquire an increased susceptibility to a certain poison, acetonitrile; this increased susceptibility he believes is due to an added power of the body to break up the acetonitrile molecule, this in turn being explained by an increased power of oxidation on the part of the body. He considers this effect an evidence of an injurious action.

Now how are we to interpret these experimental evidences of alcohol damage? Surely we can not disregard them. But yet it seems to me that some increase in uric acid output and some increase in the oxidative processes in the body need hardly be considered as matters of grave concern, when we remember that the subjects in the Atwater-Benedict and similar experiments, went through the experimental tests with no evidence of any impairment of health or function.

There is another line of work which has been carried out in relation to a possible injurious action of alcohol. This is its effect on the course of infections. Dr. Abbott,[8] in Philadelphia, gave alcohol to rabbits before or after infection with *Streptococcus pyogenes, Bacillus coli,* or *Staphylococcus pyogenes aureus.* In the infection with *Streptococcus pyogenes* the mortality of the alcohol-treated rabbits was very much greater than in the controls. In the infection with *Bacillus coli* the mortality was also greater in the alcoholized rabbits than in the controls. In the inoculations with the *Staphylococcus pyogenes aureus,* the results were not clear cut. In these experiments the dose of alcohol, 5-6 cc. per kilo, was purposely selected as an intoxicating dose. In another very extensive series of experiments performed on different species of animals, dogs, guinea pigs, rabbits, mice, pigeons, Laitinin[9] studied the effects of alcohol administration on the susceptibility to anthrax and tubercle bacilli and diphtheria toxin. He reports a marked increase in mortality among the animals receiving alcohol. Laitinin also gave large doses of alcohol in his experiments. A great number of other experiments have also been made along this line, and in general the results are in agreement with those quoted. There is one objection that can be raised against much of this work, namely that the amount of alcohol given was excessive. For example a dose commonly used was 5 cc. per kilo. This dose, calculated for human beings in relation to body weight, would be equivalent to single doses of a pint or more of whisky for the average adult. It must be admitted, however, that in some of the experimental work, with similar results, the dose was within what would be considered therapeutic limits, but Laitinin[10] himself, in a later work in which small doses of alcohol were given, was unable to demonstrate any very definite injurious effect from the alcohol. I think, however, in consideration of all this work, we may accept as proven, that under the experimental conditions present, animals receiving large or moderate doses of alcohol show a lessened resistance to bacterial infection.

While these results point a definite warning, their direct transference and application to infections in

man is another matter. Corresponding human experiments are out of the question. Further, it can hardly be claimed that human infection, with a period of incubation allowing of a gradual formation of defense mechanisms, is a duplicate of these animal infections, where an almost overwhelming quantity of bacteria is suddenly injected into an unprepared host. We have, in short, no reliable evidence that alcohol in moderate doses lowers the resistance in infectious disease. We may, of course, come to an opinion in this matter through careful clinical observations. I think we all can agree, however, that there is no unanimous belief among clinicians that alcohol properly given causes an increased mortality in human infections. I may quote in this connection a few statements from men of large experience and keen powers of observation.

Hare,[11] in a special study of the subject, concluded not only that alcohol did not lower resistance, but that it even had a power of combating infectious diseases. Meltzer,[12] another careful observer, who also had the advantage of a pharmacological training, tells of treating a large number of typhoid fever patients with alcohol without losing a case, and while he does not state that the alcohol effected a cure, he quotes his experience as showing that it did not lower the resistance to the infection. Abraham Jacobi[13] stated: "I have known for a long time that unless I give large doses of alcohol in sepsis, my patients die. If I do give it, they are apt to get well."

Statements such as these might be multiplied indefinitely. Opinions to the contrary may also be easily obtained. I quote these because they show at least a fixed conviction among many able clinicians that alcohol in suitable quantities does not lower materially resistance to bacterial infections.

I may summarize this phase of the subject as follows: Alcohol has a definite value as a food, and can be used for this purpose in amounts which have no injurious effects sufficient to offset this value.

I pass now to the third consideration, the effect of alcohol on the circulation. There is also a great amount of experimental data on this subject. In general, animal experiments, with an intact circulation, show no appreciable effect from alcohol in small or moderate doses. The pulse rate, the blood pressure, the cardiac contractions, may undergo some slight variation, but this is not constant, and there may be at one time an increase, at another a decrease. One is justified from these experiments in the belief that alcohol is not a direct circulatory stimulant. More special experiments such as those of Dixon[14] on the perfused heart, show that alcohol strengthens the contractions when the heart has become weakened, particularly if the animal has been given alcohol previously, but Dixon, rightly it would seem, ascribes this effect to the energy yielding properties of alcohol rather than to a direct stimulation. In studies on human beings the results are equally negative. In typhoid fever, Cabot[15] failed to obtain a change in pulse rate or blood pressure from alcohol. Lieb,[16] in a series of hospital cases, found no evidence of a reflex or direct stimulation, as shown by blood pressure changes. I venture to say, however, in this connection, that the change in blood pressure is not a safe criterion of the action of a drug on the heart. If we estimated the value of digitalis in relation to its power of raising blood pressure, it would hardly occupy its present place.

There is one action of alcohol which may be pointed out. This is the flushing of the skin from a vasodilatation. This occurs, as is readily understandable, with no change in general blood pressure and no change in cardiac contraction. It means a certain redistribution of blood. This action is not peculiar to alcohol, as it is obtained from a number of other substances. It is easy to ascribe too great an importance to it, but on the other hand it may in some instances have a definite value.

I may summarize this division of the subject as follows: There is no evidence that alcohol is a direct stimulant to the circulation. Through its effects as a food, and through a redistribution of blood, it may be of value in circulatory disease.

In this very limited review of the pharmacology of alcohol, I have endeavored in as concise and simple a manner as possible to draw such conclusions as were definitely warranted by experimental fact. In turning now to the clinical uses of alcohol, we must enter more into the realm of individual opinion, the value of which is often questionable. On the one hand, impressions superficially formed, quickly ripen into opinions, which in turn easily change to convictions. These often die hard. On the other hand, there is a decided tendency at present in therapeutics to believe only in those drugs for which a definite action can be shown experimentally. This is undoubtedly due to the modern development of Pharmacology. The usefulness of this tendency need not be questioned, but at the same time it may be pointed out that there is a proper mean between doing too much and doing too little for a patient. Drug therapy may well be put on a basis of pure science, but there still should remain something of the art of healing. We might well imitate Wilkes and decide first in relation to the individual case whether a drug does good, does harm, or is valueless.

In the discussion of the clinical value of alcohol it is not my purpose to describe the many uses to which it has been, and still is, put. The number of these shows a decided diminution as time goes on, which is not without significance. But it is not necessary that a drug have an unlimited number of uses in order that it be considered of value, nor is it necessary to establish its benefits in mathematical terms. All I shall attempt to show is that alcohol in two instances at least has some value in therapeutics.

I believe it possesses a definite value in typhoid fever, and this as a food. We make special efforts now in this long drawn out disease, to maintain the nutrition of the patient. This is by no means always an easy task. If by the addition of alcohol, we can increase the diet by 500 or more calories, if we can to any degree stimulate the appetite for other food, we have accomplished a useful service. It is not denied that some patients do not take kindly to alcohol. It is conceivable that it may do harm in others. Certainly its enforced administration should not be a routine procedure. But, in spite of this, it seems to me well proven that alcohol is of value in the treatment of typhoid fever.

I believe there is another sphere of alcohol usefulness, namely in circulatory disease. I recall

a statement made by Dr. Emmett Holt last summer to the effect that there were three things to consider in the management of the average case: the treatment of the disease, the treatment of the patient, and the treatment of the family. Now while the pharmacology of alcohol may give no basis for its use in the treatment of the disease, there is ample clinical evidence of its value in the treatment of the patient. Those who have observed its effects in relieving anginal attacks can not fail to be convinced that it is a useful remedy. Whether it does this by action on the cerebrum, by causing a redistribution of blood, or in some other manner, whether other drugs or measures would bring about the same beneficial effect, all this is beside the point. The fact remains that it is of value in these cases, and that the benefit is not accompanied by any discernible injury. I might mention other conditions in heart disease in which there can be no question that alcohol has been of benefit to the patient, but it seems unnecessary to enter further into a discussion of this phase of the subject. I trust I have made it clear that there are good reasons for the conclusion that alcohol has a value in therapeutics.

There is another matter I should like to touch upon before concluding. There are signs at present of a growing desire on the part of some individuals and some groups, to restrict by legislative proceedings the drugs a physician may prescribe in his practice. Such a restriction has already been made in the case of alcohol. The question here of course is intimately connected with the more general one of prohibition. Without entering into a discussion of the merits of prohibition, or the necessity of medical restriction in enforcing it, I think that the medical profession should vigorously oppose such restriction. A majority opinion as to the value of any particular drug does not necessarily carry any more weight than a minority one. A physician in charge of a case automatically assumes full responsibility for it, and he should in no way be hampered in his management, provided he acts in good faith and to the best of his ability and judgment. There should be laws in force which inflict a sufficient penalty on those who through ignorance or cupidity fail to safeguard the welfare of their patients. But it seems to me that the principle of restricting the legitimate use of drugs is a bad one, that it will react badly on the profession, and that it ought to be actively combated.

THE IMPORTANCE OF ENDOCRINE THERAPY IN COMBINATION WITH MENTAL ANALYSIS IN THE TREATMENT OF CERTAIN CASES OF PERSONALITY DEVIATION.*

By EDITH R. SPAULDING, M.D.,
NEW YORK.

It is with the group of cases in which other organic disease has been as far as possible ruled out but which still show the presence of glandular imbalance that we are primarily concerned in this paper. At the present time the patient who suffers from an endocrine disorder, which is associated with mental symptoms, rarely is given the benefit of both glandular treatment and a mental analysis, utilized concomitantly as necessary elements of a rational scheme of re-education. The endocrinologist even though he may appreciate the close relationship between the personality and the glands of internal secretion is anxious to control his treatment and estimate its results by eliminating as many confusing factors as possible. If the case shows signs of glandular imbalance which he considers sufficient to cause the mental symptoms, he naturally enough wishes to show the value of endocrine therapy alone in correcting the condition. The psychiatrist who approaches the problem from the point of view of its psychogenesis is, on the other hand, usually able to find sufficient cause in the life experiences of the patient and in his adjustment to them to account for much of the abnormality found. Even as unsubstantiated as some of the psychogenetic theories may still be considered by certain physicians, the psychiatrist may criticize, to even greater extent, the supposed rationalizations of the endocrinologists. Many psychiatrists will prefer to trust the known uncertainties of the mental theories than to risk what seem to them the unknown uncertainties of the endocrine theories. Furthermore, the amount of time required to enable the examiner to consider either aspect of the situation thoroughly is so great that it may easily be made an excuse for having but one aspect considered at a time. For the endocrinologist has not often the time to devote to the intensive delving into the past that is necessary in a thorough mental analysis, while the psychiatrist as well as the patient may consider the extensive metabolic studies and *x*-ray examinations an unnecessary luxury.

If the psychiatrist is not familiar with the practical application of glandular therapy he will doubtless feel the need of consulting the endocrinologist, in which instance he may fear a division of the "transference" and a consequent lessening of his power to obtain results on a purely mental basis. For these as well as for other reasons the patient is but too often treated from one point of view or from the other, only and even when both forms of therapy are utilized, they are seldom used synchronously. Again there is among the general practioners as well as among the various specialists, much prejudice to be overcome, which prevents in many instances the thorough utilization of either of the two forms of treatment.

*Read before The Medico-Psychological Association held in Boston, June, 1921.

While the experimental work that has already been done has shown the close relationship between the emotions and the glands of internal secretion, it has not been carried far enough to give in many instances a satisfactory basis for treatment. It is probable that from the involved and obscure nature of the problem it will always be necessary to base therapy to a certain extent on data obtained empirically. However, the fact that certain relationships between the sympathetic nervous system and the emotions are found to be fairly constant gives, in itself, a basis on which to build, while the therapeutic results already obtained in definite conditions such as myxedema, hyperthyroidism, hypopituitarism, and status thymico-lymphaticus suggest a promising foundation for the treatment of the innumerable deviations which individual cases present.

While a close relationship is recognized in such types as these, between the emotions and the vegetative nervous system, a similar relationship of great importance is also observed between the vegetative nervous system and the personality development. For instance, in the hypothyroid condition there is often found a sluggish mentality and slow physical response while an overactive mental state and rapid physical response is associated with the hyperthyroid condition. Associated with such increased activity are frequently found fears and apprehensive states, great susceptibility to noise, and periods of excessive fatigue when the too quickly used energy is exhausted. With the resulting temperament there is great difficulty in making the adjustments of every-day life. Such patients soon lose confidence in themselves when they realize the erratic things they do and say when under the tension of their overactivity; and their physical and mental incompetence, when the fire has burned out and they show temporarily a glandular underactivity, is equally undermining to their fund of courage.

Again in the Fröelich type of dyspituitarism as well as in certain other types of glandular imbalance, the secondary sex characteristics of a reversive type are frequently associated with the mental characteristics and tendencies which correspond. The boy is soon known as a sissy among his playmates. He is not up to the standards of the others in sports. He seeks the protection of his home, oftentimes of his mother, or he tries to compensate for his inadequacies through books or the world of his imagination and emotion. Later on in life such types are found making difficult marital adjustments or perhaps experiencing emotion only for members of their own sex. While the Freudian theories will undoubtedly explain and help in untangling certain types of homosexuality there are others that may be explained by glandular deviations. Such personalities may easily feel that society is failing to give them a fair deal since their spontaneous emotions are facilely dubbed perversions.

According to Timme there is frequently associated with hypopituitarism a lack of inhibition of the emotions. Such cases show much excitability on little cause, which alternates with sluggishness, frequently have phobias and compulsions, such as kleptomania, and show moral and sexual obliquities.

In cases which habitually have low blood pressure, inadequate circulation, frequent headaches, perhaps migrainous in type, enteroptosis with insufficient intestinal activity, and great fatiguability, it is quite natural that there should follow a feeling of general inadequacy in meeting the problems of life and making adjustments. The attitude that results is not one which welcomes difficulties but rather one which more and more tends to establish protective mechanisms until the individual's activities are limited to the narrowest possible circle of physical, if not also of mental endeavor.

These are a few of the more obvious situations in which there appears to be a close relationship between glandular imbalance and personality development. Adler has pointed out the many traits that may result from glandular inadequacy and the various adaptive mechanisms to which the child resorts in his efforts at compensation. Other aspects of the inter-relationships have been shown, but there still remains an almost unexplored field in the study of personality to be reached by the psycho-physical route.

The following five cases are cited to demonstrate the value of endocrine therapy together with mental analysis in (1) a case of manic depressive psychosis, (2) a psychopathic personality with episodal attacks, (3) a psychoneurosis showing antisocial tendencies, and (4) a case showing emotional imbalance in a girl who had utilized physical conditions in which there was a glandular element to protect herself against unpleasant social situations.

Case I.—Miss S., aged 17, presented a mild depression of the insufficiency type with some physical and mental inadequacy, mental retardation, decreased psychomotor activity, suicidal ideas, and ideas of self-accusation and self-depreciation. There was gradual improvement and finally complete recovery following the combination of glandular therapy and mental analysis. The patient had had three depressive attacks, two of which were precipitated by mental stress and one by influenza. There was a history of irregular menstruation, inadequate intestinal action and great fatigability. The physical examination showed a girl of small stature, small hands and feet, small blood vessels, and hyperextension of the joints. Examination of the blood showed the sugar content to be 108 milligrams per cubic centimeter. The coagulation time of the blood was 11 minutes and the carbon dioxide combining power of the plasma was 61.7 per cent. The differential cell count showed polynuclear neutrophiles to be 44.4 per cent., small lymphocytes 40.0 per cent., large mononuclear lymphocytes 3.8 per cent., and eosinophiles 3.2 per cent. The blood pressure was 110/80. The x-ray examination of the skull showed a normal sella turcica. The increase in coagulation time, decreased leucocyte count and increased lymphocyte count, in an absence of organic disease, the history of irregular menstruation, inadequate intestinal action, fatigability, and the low blood pressure were some of the symptoms that pointed to a disturbance of glandular activity.

This case was considered one of hypopituitarism in which there had also been a subinvolution of the thymus. In spite of the psychogenetic factors which called for a rather intensive and extensive course of mental analysis, the mental sluggishness was helped by the administration of whole gland pituitary. During the year that this patient has been holding a position of responsibility in the community, the mental retardation has tended to recur whenever the pituitary has been discontinued for any length of time.

Case II.—Margaret B., age 14, who presents a combination of physical, mental, and endocrine symptoms, is a defective, psychopathic girl of fourteen who was

subject to daily episodal attacks of excitement which were precipitated chiefly by her inability to have her own way. Although the constitutional defects in this case must be regarded as of importance, the social behavior was aggravated by an injudicious home training. This girl was brought reluctantly by her mother because of her increasing number of tantrums and screaming attacks, her violent temper and her assaultiveness. The family were afraid that she would do some permanent injury to her younger brother and sister whom she had often kicked and attacked with heavy sticks of wood. She injured herself by biting, pounding her legs and breasts, and sticking a nail file into her breasts, all to gain her mother's sympathy. The mother admitted that the child masturbated excessively.

The family history showed a tendency to thyroid and pituitary disorders although there were no other cases of mental defect. As a child the patient was never as strong as her two sisters and her brother, her musculature was not well developed, and at an early age an internal strabismus was noted. The general feeling of the family is that she was not normal from birth, and although she did not cry much, she slept little. At three and a half years she was hit by a speeding automobile, had a fractured clavicle, and was unconscious for a short time. When five years old she was operated on, with rather poor results, for strabismus but refraction has tended since then to decrease the defect. There was a history of chronic intestinal stasis with distention and much mucus in the stools. The periods of irritability were aggravated by the intestinal condition. The voluntary retention of urine was also a factor in her irritability.

Physical examination showed a girl of 14 years of age who was nearly six feet tall and much over-developed sexually. There was over-development of the bony structures, disproportion in the leg torso ratio, long, thin hands and feet, a nasal brow, absence of one lateral incisor, slight facial acne, oily skin, excessive perspiration, cold, bluish extremities, hair of coarse texture, a hairy growth on the extremities, a masculine distribution of the pubic hair and tendency to a mustache. The thyroid was enlarged and there was a tremor of the hands and a rapid pulse, which increased with exertion and apprehension and was associated with no organic heart lesion. There was cessation of the menstrual period for several months at a time. On stroking the chest there was a marked red line with a pronounced white border. The psychomotor coordination was exceedingly poor.

Examination of the blood showed a high color index and hemoglobin content, although the patient looked anemic at times and was especially pale after exertion and fright. She showed a fatiguability out of proportion to her robust appearance. The cell count showed an increase in large mononuclears and a decrease in polynuclear leucocytes. The blood sugar was 1.33 per cent. and the carbon dioxide tension was 60 per cent. X-ray of the skull showed a slightly enlarged sella turcica with marked erosion of the dorsum sellæ. The blood Wassermann and Wassermann of the spinal fluid were negative.

According to the Binet-Simon scale the patient graded eight years and six months while her chronological age was thirteen years and eleven months. This gave her an intelligence quotient of 0.65, which placed her in the feeble-minded group. Margaret showed considerable ability in drawing and much appreciation of good music, both of which traits could be utilized to advantage in her daily schedule. A psychological examination at the end of three months training and treatment showed that she had gained six months in mental level, and gave evidence besides of much improvement in attention, effort, and judgment.

Although there was evidence of much glandular imbalance in this case, the endocrine factors were considered by the endocrinologist who saw her as a small part of the cause of the total picture. (Margaret threw herself on the floor in rage during the consultation when she felt that sufficient attention was not being paid her.) However, without the help that was received from counteracting the overactivity of the thyroid alone the task of reconstruction would have been even more difficult than it was.

During the first few weeks of Margaret's residence with us it required continual effort to prevent situations from occurring which would precipitate tantrums. She was in a constant state of restlessness and irritability, and frequently expressed the desire to be at home where she "would not have to behave," and where she could have her own way. During this time she was untidy in her habits, considering the most primitive of acts the greatest possible joke. When reprimanded for something she was doing she would scream loudly and continuously, throw anything within reach, especially hair brushes, pound herself and threaten to cut off her breasts.

The most important part of her reeducation was the facing of each situation as it arose every minute of the day. Wet packs proved helpful and deprivation of privileges contributed their share toward correcting the screaming and assaultive behavior, the self-mutilation, the teasing and the incessant repetitions of questions and the answers, all of which had been used as secondary mechanisms to obtain what was considered unobtainable by less forceful methods. The episodes of excitement decreased very gradually until from being almost continuous she was having only one a day and at the end of her residence with us, none. As the improvement continued it was possible to keep her up to a higher standard of behavior and help her to face greater issues. There was a definite improvement in psychomotor coordination and in posture. The educational procedure utilized in this case besides academic work included gymnasium, typewriting, piano playing and dancing. With the treatment administered the pulse came down from 120 to 80, the palpitation decreased, there was much less dyspnea, the pink line on the chest became less intense and the white border less marked. The blood pressure was reduced from 128/85 to 110/80. More important still was the fact that the general mental and physical tension decreased. The patient was not so apprehensive at night or when walking through traffic. Furthermore, there was not so much actual distress at noise. The sleep was increased from four or five hours to nine or ten. The sedatives which were used in the beginning seemed to have little effect and were soon discontinued.

While this case presented a congenital defect the cause of which could not be determined, the reeducational procedure that proved most beneficial was one which took into consideration both the endocrine imbalance and the need of mental therapy.

Case III.—Mrs. M., a woman of forty, was referred because she had taken small amounts of money and articles of clothing from the home in which she was employed as a matron. She was also found to be corresponding rather energetically with a married man whose wife objected. The patient had slept but a few hours each night for a period of months and had had continual headaches with migrainous crises, very severe in nature at frequent intervals, irregularities of the menstrual function and a continued feeling of tension and apprehensiveness, hot flashes and palpitation.

Physical examination showed a fairly well developed woman of the tall thin type. The eyebrows showed very perceptible thinning over the outer third. The teeth of the lower-jaw were crowded. The pupils were large and reacted slowly to light. The reflexes were exaggerated and there was a tremor of the hands. The blood pressure was 160 systolic and 110 diastolic. The Wassermann of the blood, the blood count and the urine examination were negative. X-ray of the skull showed the sella turcica to be of average size with no visible erosion. There was, however, a tipping forward of the posterior clinoids. There was a marked limitation of the visual fields, most marked in the left temporal region, which improved under treatment. The patient complained of unconsciously walking toward the left on the sidewalk, a symptom which disappeared as the condition improved. The fundi were normal. Timme has reported a case of dyspituitarism* similar to this

*Timme, Walter: Dyspituitarism with limitations of the visual fields; symptoms disappearing under the use of internal glandular therapy.—Contributions of the Neurological Institute, Vol. III, page 151.

in which there was limitation of the fields which responded to pituitary feeding.

The following social history was obtained. The patient was a widow with two children who were dependent on her for support. Her husband had had tuberculosis of the larynx, had been alcoholic the last years of his life and finally, after months of threatening, had committed suicide by turning on the gas. He had had during their entire married life nocturnal epileptic attacks following which he had been irrational and had clutched at her wildly, filling her with terror. All of this she had kept to herself, being ashamed to admit it even to members of her family. She had devoted herself to him, hoping that she might be able to protect him and his reputation from them all. She was, furthermore, a very repressed person who still felt inhibited in the presence of her mother, had never been able to make a satisfactory marital adjustment and was over-conscientious in most of her judgments of life. Following her husband's death she had indulged the maternal instincts, that were not exhausted in the care of her children and the babies in the Home, by listening to the domestic difficulties and business troubles of a man who had been a family friend. The friendship had no further emotional content than this notwithstanding the fact of its being the source of some discomfort to the wife. It was easily abandoned. In spite of much economy and hard work it was difficult to make ends meet in caring for her family, for besides the regular expenses there were debts of her husband's that she dreaded to have known and was trying by degrees to pay off. The combination of physical and mental pressure was so great that she lost her sense of proportion and was tempted to take things, to help out the home situation, acting in a way that was incompatible with the type of woman she represented.

It is doubtful if either mental analysis or endocrine therapy alone would have helped this patient to regain her social equilibrium. The pain in the head and associated feelings of confusion responded to endocrine therapy (pituitary and corpus luteum being utilized with sodium bicarbonate), and the feelings of tension, the sleeplessness, and the vasomotor disturbance disappeared. It was possible through mental analysis to give great relief to this woman who had repressed her emotions to such an extent since her earliest childhood. As she said, "I suppose the medicines do good" (she had a strong prejudice against them), "but it is the talks that seem to help me most." Considering the improvement in the visual fields as well as in the other subjective symptoms, it may be inferred that the physical help was quite as important as the mental therapy.

The following case was referred through the courtesy of Dr. Ludwig Kast, to whom I am indebted for permission to make use of his records in this paper:

Case IV.—Elizabeth F., a girl of fourteen, had had intestinal attacks causing such distress that it had been necessary for her to leave boarding school. As the attacks recurred when she was separated from her family, she had remained at home most of the school term where she had had frequent tantrums and had even thrown books at her mother of whom she was exceedingly fond. One year previously she had on several occasions set fires, which nearly terminated fatally.

The following history was elicited: Ten years previously the mother had become somewhat estranged from the father and had made up her mind to devote her life in the future to her two daughters. As she expressed it, she gave to the older "all her intellect; to the younger all her emotion." Elizabeth, who was the younger of the two, grew up in the warmth of this great emotion and, furthermore, was able to obtain whatever she wished from both parents. There existed with Elizabeth, however, considerable jealousy of the older sister who was closer to the father in her sympathies than Elizabeth was. Early in life she learned that she could rule her parents through her emotions and she continued to take advantage of this until the maelstrom of her adolescent emotions became so great that it was no longer easy to separate cause from effect. After the fires occurred she was examined by a psychologist who advised her going away from the family and especially from the mother. She was consequently sent to a summer camp but for one month only. She then went away to boarding school. While there, however, she cried most of the time and was very dependent on the daily letter she sent home. She admitted that she missed greatly the constant demonstration of affection with which she was surrounded when at home. Her menstruation stopped for a period of three months and she began to have intestinal and digestive attacks in which there was intestinal stasis associated with distension. Cathartics and enemata were of no avail. It seemed necessary for her to return to her mother, which was the thing above all others in the world that she desired. Fearing that she might have a return of the symptoms the parents allowed her to remain at home for four months of the term.

Physically, Elizabeth presented symptoms of glandular imbalance including some of the characteristics of hypopituitarism. She was small and stocky in build, having gained some forty pounds in weight during a short period following an operation for appendicitis. The eyes were somewhat near together and there was a tendency to a nasal brow. There was some disproportion in the leg-torso ratio. On stroking the chest there was but a faint pink line. There was a history of urticaria, nose-bleeds, extreme fatigability, painful and irregular periods from the time menstruation was established and intestinal attacks which increased in severity during the menstrual period. She also showed a predisposition to frequent infections of the respiratory tract. The appendix had been removed two years previously but no adhesions or constrictions of the intestines could be found by *x*-ray or seen fluoroscopically. The sugar content of the blood was 0.74 and the hemoglobin was 0.75. The other laboratory tests were all negative.

Intellectually Elizabeth was fourteen months retarded which gave her an intelligence quotient of .91. Although she had moved much from school to school it was in the tests of native ability and those requiring reasoning power that she did poorly as well as in those that were dependent to some extent on training.

In this case there apparently occurred, because of the extreme homesickness from which the girl suffered, a general glandular inactivity which was evidenced by the cessation of the menstrual periods as well as by the intestinal inactivity. The girl's early history gave evidence of a predisposition to glandular imbalance. When a means of escape from an intolerable situation was presented through physical symptoms they were magnified more or less consciously until they became a means to the end desired, namely, again living in the atmosphere of intense emotion and adoration offered in the home.

Elizabeth was given small doses of pituitary with the result that for the first time in months her digestion returned to a normal condition. When this excuse was removed she was helped to see how much was to be gained by returning to school, in the way of preparation for a course of nursing later on.

Elizabeth then made a satisfactory adjustment at school for the first time, stating that the thing that helped the most was looking forward to the time when she could become a nurse. Her mother was made happier than she had been for years because of her attitude when she returned from school. Although the improvement is marked, a plan of procedure has been mapped out for the next two years which will help her to keep her balance through the difficult years of adolescence. The glandular therapy is being continued with the same good results.

A case similar to this, also referred by Dr. Ludwig Kast, was that of a boy of nine, who also made use of an intestinal condition in order to avoid an intolerable situation in his school and exaggerated his symptoms which were originally physical in na-

ture. He had remained at home most of the winter. He, too, admitted frankly that his condition would not have been sufficient to keep him at home, had the school situation been a pleasant one. There was evidence of glandular imbalance in this case as well and correlated with it a strong tendency to compensate through a world of imagination for the everyday adjustment with his schoolmates which he found too difficult to make.

In such cases as these the underlying physical inadequacy is too often underestimated in its effect on the social life of the child. The greatest possible emphasis should be laid on the social adjustment which is necessary to counteract any associated feelings of inferiority.

Conclusions.—There are a large number of psychoneurotics and social deviates of various kinds who have been socially inefficient for years. They have gone from medical man to surgeon, from neurologist to psychiatrist, but have failed to regain their nervous equilibrium because their need has been so definitely twofold in nature. For when their glandular balance has been recognized, the fact has not been appreciated that they have formed compensatory mechanisms and conditioned reflexes that must be treated from the mental side alone. It is only when the twofold adjustment is made that they can reach their highest degree of efficiency as integrated personalities.

TURPENTINE BY INJECTION IN DERMATOLOGY AND UROLOGY.*

By JOSEPH L. TENENBAUM, M.D.,

NEW YORK.

The imperfect state of therapeutics makes every new suggestion, whether based on scientific facts or empirics, worthy of serious consideration, and this furnishes sufficient ground for the interest aroused in the method of injections of turpentine, first advocated by Klingmüller in Germany. He was prompted to revive the use of this old therapeutic agent by the newer conception in therapy, especially developed in Germany.

Since 1895, when Matthes introduced the milk injection therapy, resulting in reactions similar to those obtained from tuberculin, there have accumulated more and more proofs bringing into doubt the previous conception of specific therapy.

Before that Rumpf reported good results in typhoid by applying a non-specific heterovaccine of pyocyaneus, and later v. Wagner recommended tuberculin in paresis, which in association with mercury is still his method of choice in the treatment of this disease.

Then followed the era of autoserum therapy in skin and other diseases, and during the last few years numerous protein derivatives, colloids, and chemical substances have been recommended which had for their object the stimulation of the natural forces of the body in overcoming disease. Turpentine is one of them—a link in the chain of remedies belonging to the group of protein therapy, stimulating treatment, or whatever term one may chose to call it.

Klingmüller's first publication appeared in 1917[1], and was supplemented by a further communication in 1918[2]. In these the author details his observations in a large number of cases which he subjected to treatment with turpentine oil in 10 to 20 per cent suspension, and in doses varying from 0.1-0.4 c.c.

In brief, his experience may be summed up as follows: In acute anterior urethritis a dose of 0.2 c.c. was sufficient to check the discharge, but he points out that the remedy had no effect upon the gonococci directly, thus making the use of local treatment necessary. In gonorrheal polyarthritis and tendovaginitis, remarkable results were obtained. This was not found to be the case in acute epididymitis and posterior urethritis, where the injections proved a possible source of serious complications.

So far as its use in dermatology is concerned, Klingmüller has obtained excellent results in furunculosis, folliculitis barbæ, impetiginous and infiltrating eczema of the extremities, acne, pityriasis, rosea, lichen planus, impetigo contagiosa, etc. Noteworthy were the results in trychophytosis, where one injection was sometimes sufficient to cause a complete disappearance of the lesions. Scrofuloderma and lupus vulgaris responded to a lesser degree, exhibiting similar reactions to those obtained with tuberculin, and even in cases of unknown etiology, as certain types of acute dermatitis, strophulus infantum, urticaria, etc., turpentine proved of benefit. In addition he found it useful in cystitis, in certain types of pyelitis, and in inflammations of the parametrium.

Klingmüller's work was soon followed by numerous studies, and as is usually the case, there have been enthusiasts as well as skeptics. Among the authors who consider his method more or less successful may be mentioned: v. Brölemann, Sellei, Gravisch, Meyer, Holzhauser, Werner, Sfakianasis, Becher, Karo, Appel, and Assmann. On the other hand Pürkhauser, Schubert, Ruette, and others express disappointment with this remedy.

The affections that were originally subjected to this therapy were soon augmented so as to include Duhring's disease, pemphigus, erythema exudativum multiforme, bubo, chancroid, and certain gynecological and surgical diseases.

Theoretical Considerations.—The theoretical considerations which underlie the use of turpentine may be briefly summarized as follows: Chemically turpentine belongs to the group of terpenes ($C_{10}H_{16}$), which is the principal constituent of the so-called "essential oils." As is well known, the essential oils possess the power to produce irritation when locally applied, and have also the ability to produce active hyperemia. While some of the terpenes are more or less bactericidal, there is little evidence to support the view that turpentine possesses this quality. The most striking property of turpentine is its remarkable *chemotactic* action on *leucocytes.*

Interesting in this respect are the experiments of Heinz[3], who noted a marked increase of the leucoblastic tissue of the bone marrow after the intra-

*From the Dermatological Department of the Mount Sinai Hosiptal, Director Dr. Herman Goldenberg; Service—Dr. L. Chargin; and the Genito-Urinary Department of the Vanderbilt Clinic, Chief, Dr. Alphonse A. Wren. Received for publication November 30, 1921.

venous injection of 10 per cent turpentine emulsion into a guinea pig. Based on similar facts many observers ascribed the therapeutic effect of turpentine to a leucocytosis, and particularly to aseptic abscesses caused by these injections.

Klingmüller offers numerous other explanations for the action of turpentine, but he too, in common with other observers, emphasizes the important part taken by the leucocytes in that process.

The leucocytosis theory, however, is not accepted by all authorities, and indeed, should we admit that a leucocytosis is the constant concomitant of the injections of turpentine, how can we explain its beneficial effect in non-parasitic skin affections?

To explain its action in these cases some other theory is necessary, unless we assume that the beneficial effect of turpentine is to be attributed to the breaking up of the leucocytes followed by the liberation of protein bodies acting as a stimulus. This last statement is equivalent to the conception of the non-specific protein therapy, which in fact seems to offer the most satisfactory explanation.

As pointed out before, the peculiar reaction of the body to non-specific proteins introduced parenterally can be provoked by various chemical substances, such as collargol, electragol, argochrom, iodine, etc. Whether their action is due to their own stimulating properties, or to disturbances in the proteins and colloids of the body, is not material. Their fundamental distinction, however, from other methods of treatment lies in the fact that their action is exerted not upon the etiologic factor of the disease, nor upon any one of the special organs of the body, but they apparently exert a stimulating action upon all the cells of the body (ergotropy). Leucocytosis, stimulation of the leucoblastic tissue, fever in some cases, and similar reactions are instances of hyperactivity of the tissues. Increased growth of granulation tissue, seen for instance in ulcers of the leg, is another objective sign of stimulated vitality. This explains many of the questions linked with the so-called stimulation therapy in general, and the turpentine treatment in particular.

Personal Experience.—We have experimented with a variety of affections which include the following dermatological and genito-urinary diseases: acne vulgaris, dermatitis venenata, *x*-ray dermatitis, chronic eczema, seborrhoic eczema, rosacea, impetigo contagiosa and bullosa, furunculosis, pyodermia, tinea, folliculitis barbæ, psoriasis, chronic urticaria, lichen urticatus, prurigo mitis, neurodermitis, pruritus universalis, lupus erythematosus, ulcus cruris, acute anterior urethritis, epididymitis, bubo, and a few other lesions which are not included in this paper.

So far as preparation and technique is concerned, Klingmüller's method was followed implicitly. A 10 to 20 per cent emulsion of rectified turpentine oil in pure sterilized olive oil was employed in all cases subjected to that treatment. (Terpichin, a preparation of turpentine oil deprived of the resins and oxides, in combination with quinine and anesthesine, advised by Karo, proved of no advantage in comparison with the original turpentine oil.) The largest dose used for a single injection was 2 c.c. A dose not exceeding 1 c.c. is probably the most satisfactory. The intervals of the turpentine administration varied from one every two days to one injection a week. Injections given twice weekly proved to be sufficient. The ages of the patients varied from one to 65 years.

The site of predilection for the injection is determined by a horizontal line drawn from the posterior axillary border and a line figured one to two fingers' breadth beneath the brim of the pelvic bone. At the intersection of these two lines the point of the needle strikes the periosteum easily, upon which the injection is made. Besides the usual antiseptics no other precautions are necessary.

Some authors warned against the injections on account of the danger of aseptic abscesses. The majority of these complications, however, proved to be due to a faulty technique; injecting into the subcutaneous tissue for instance, or using impure emulsions. In the many hundreds of injections which we have administered, with the exception of a few cases, no particular pain was experienced, except numbness and stiffness of the leg, lasting from a few minutes to a few hours. Practically no sign of infiltration and no general reaction could be observed.

An analysis of the results obtained in 120 of our patients suffering from various skin and genito-urinary affections leads to the following conclusions:

Lupus erythematosus and *rosacea*, owing to their chronic character, did not permit of a final estimate. Further observations will be required before passing a final judgment.

Psoriasis proved rebellious to this treatment. Not a single lesion cleared up, and despite numerous injections new lesions appeared.

Similar experience can be reported in a case of *pemphigus*. After two injections the patient refused further treatment, complaining of aggravation of the disease accompanied by severe itching. We cannot, however, draw definite conclusions, until a larger number of cases will be observed.

Lesions of *impetigo contagiosa*, the crustaceous as well as the bullous type, cleared up quickly after one to two injections with no local treatment, but new lesions appeared in spite of the injections.

In *folliculitis barbae* the optimism of various authors does not seem justified. It seems to act exactly as do the vaccines. Of four cases treated with injections, one patient did not show the slightest improvement, two exhibited temporary relief, and only one case of a rather superficial type cleared up with no relapse for several weeks.

More or less good results have been observed in *furunculosis, pyodermia*, and *suppuration of the sweat glands*. In connection with furunculosis the following case is most instructive. When first seen the patient, a young anemic girl, presented a furuncle of the cheek, the size of a plum. Following the first injection the inflammatory process subsided in a few days, and an indolent pea-sized area was all that remained of the former lesion. One week later, however, there was a recurrence with intense inflammation of the surrounding tissue. This seems to indicate, as already pointed out, that turpentine affects the secondary products of the inflammation rather than the causative factor.

In *tineas*, the superficial, and particularly the deep type, turpentine proved of assistance in asso-

ciation with local treatment. Cases treated with turpentine and 3 to 5 per cent resorcin paste healed quicker than with other methods of routine treatment, *x*-ray excepted.

Good results have been obtained in some cases of *acne*. Deep seated, indolent, small abscesses of *acne indurata* yielded readily, and a few injections caused complete involution of the process. No local treatment of any character was employed in these cases. The products of suppuration were resorbed, but new lesions appeared in some of the cases, which as a rule subsided on further treatment.

As an example may be cited in the patient, T. A., female, 21 years old, who was under observation since 1917—a period of four years. Diagnosis: acne indurata. Routine treatment followed up, off and on, proved of little value. Immediately prior to treatment with turpentine her face was covered with many pustules, small abscesses, and deep seated purplish tubercles scattered over chin and cheeks. Two injections were followed by marked improvement, as exhibited by the fact that most of the old-standing lesions were involuted, but then there appeared a few new lesions. With seven injections the process was practically healed, and thus far there has been no recurrence.

Not so striking have been the results in the superficial type of *acne simplex*. The papules and small pustular lesions proved much more resistant than those in acne indurata, some of the cases showing little improvement.

The most satisfactory results have been noted in *ulcera cruris*. Several cases, which had been for a number of years subjected to various methods of treatment without lasting benefit, have improved on turpentine injections in a short period of time. Some of them presented inveterate ulcers with unclean bases and sclerosed borders; others were associated with weeping eczema, covering the lower and middle thirds of the leg. All these types showed marked improvement, with the exception of ulcerations in a case of acrodermatitis atrophicans. In the majority, a single injection was followed by a clearing of the base of the ulcer, and by a springing up of new granulations, which with continued treatment ultimately covered the entire surface.

No less remarkable has been the improvement of the subjective symptoms. Pain and itching, accompanying the progressing disease, disappeared with the first injection in most instances. This was particularly noticeable in one patient who was hardly able to move his leg prior to this treatment, and who was enabled to get about without discomfort a day after the injection had been administered. In all cases a certain euphoria was undeniable. At most 7 to 10 injections proved to be sufficient for a cure, so far as one can speak of a cure in this chronic and recurrent affection.

In the *urticaria group*, including *lichen urticatus* and *prurigo mitis*, and in the so-called neurodermites the results are not uniform. Certain individual and constitutional factors influencing the course of treatment seem to play a more important role in these cases than in any of the other skin affections.

A case of a generalized *lichen urticatus*, suffering for years from that disease, was very much benefited. But in general the disappointments were as numerous as the apparent successes. The same may be said in reference to *prurigo mitis* in children.

The *eczema* group, except a drying up effect on weeping and impetiginous lesions, did not encourage further trial.

A case of generalized *dermatitis venenata* was cured with four injections without local applications.

In *genito-urinary* diseases turpentine deserves a prominent place as a therapeutic agent. In acute anterior urethritis a few injections given at intervals of two days sufficed to check the discharge almost entirely, and thus made the use of local remedies in acute inflammatory conditions of the urethra a comparatively easy task; but no direct effect whatsoever was noted upon the gonococci. In chronic gonorrhea it proved of little value.

Among other genito-urinary diseases, *epididymitis* was very favorably influenced. The reaction was prompt and the patients felt noticeable relief 6 to 7 hours after the injection.

A case which is most instructive in this regard, is that of patient C. T., age 20, with no history of previous infection, who contracted gonorrhea, and six weeks later developed a right-sided epididymitis about the size of a fist with the minor globus adherent to the scrotum. Urethral discharge was positive for gonoccoci. Two days following a single injection, the intense inflammation and tenderness subsided, the swelling was reduced by one half, and the epididymis was freed from adhesions. It required, however, a longer period for a total cure. In chronic epididymitis also turpentine proved of value.

Striking results have been obtained in a case of bilateral *bubo* complicating chancroid. Within 24 hours following a single injection the threatening suppuration was averted, all pain stopped, and the swelling subsided rapidly.

Similar experience has been noted in *gonorrheal lymphadenitis*.

Conclusions.—1. Injections of turpentine act on disease by exerting a stimulating effect on the general vitality of the system.

2. Although not enthusiasts, our experience leads us to the conclusion that the injections of turpentine are valuable in the treatment of pyogenic infections of the skin, and in gonorrhea.

3. Furthermore, this remedy was found useful in acute inflammatory affections of the skin as well as in chronic exudative lesions.

4. The best results were noted in ulcers of the leg, and in epididymitis.

The writer wishes to express his thanks to Drs. Herman Goldenberg, Alphonse A. Wren, and especially Louis Chargin for their valuable suggestions and cooperation in connection with this work; and to Dr. Ph. B. Bregman for his assistance in the course of the study.

CASES OF SO-CALLED TROPICAL GRANULOMA OBSERVED IN KINGS COUNTY HOSPITAL.*

BY JAMES MACFARLANE WINFIELD, M.D.,

AND

LEWIS D. HOPPE, JR., M.D.

BROOKLYN, N. Y.

TROPICAL granuloma, variously called *granuloma tropicum*, *granuloma pudenda*, *granuloma venereum*, ulcerating granuloma of the groin, etc., etc., has been reported from different parts of the world, but it is more commonly seen in the subtropical and tropical countries where it is endemic, as India, the West Indies, Central America and tropical South America. It is unfortunate that the malady has not a more descriptive name, *granuloma pudenda*, *inguinale*, or *venereum* are not suitable, for the lesions may occur anywhere about the pubic region, and it is not proved that the disease is confined exclusively to the tropics.

The name we have chosen for the title of our article is not suitable in this instance, for neither of the patients had ever been in the tropics nor out of the United States, although it is possible that the woman might have been infected through promiscuous intercourse, and the man's occupation (longshoreman) would have thrown him with those from whom he might have acquired the disease. We are inclined to think that personal uncleanliness has a great deal to do with the etiology: the lowered resistance of the skin caused by dirt could easily put the tissues in a receptive state for the propagation of the special organism.

The disease was first accurately noted by MacLeod, in India, in 1882. In 1896 Conyers and Daniels, as a result of their studies of tropical ulcers observed in British Guiana, recognized it as a clinical entity. Since then many cases have been reported from various parts of the world and great advances have been made in the etiology, pathology, and treatment of the disease. The first authentic instance of the occurrence of this disease in the United States was reported by Grindon in a paper read before the American Dermatological Association in 1912 (*Journal of Cutaneous Diseases*, Vol. 31, p. 236, 1913). In 1920 Symmers and Frost reported two cases observed in Bellevue Hospital, New York (*Journal of the American Medical Association*, Vol. 74, p. 1304, 1920). A year later Campbell (*Journal of the American Medical Association*, Vol. 76, p. 648, 1921) reported two additional cases from the same hospital, and adds further observations on one of Symmers' cases. At the May meeting of the Section on Dermatology and Syphilis of the New York Academy of Medicine, Rosen (Granuloma Inguinale, presentation of a case, *Archives of Dermatology and Syphilis*, Vol. 4, No. 4, p. 272, Aug., 1921) showed a patient, a mulatto, a native of the United States, suffering from an ulcerating new growth in the groin. In spite of practically negative findings, the members present considered it to be clinically *granuloma inguinale*.

A review of the literature of the subject fails to reveal any more cases having their origin strictly in the United States, although Grindon, in the article quoted above, says that the late Robert W. Taylor claims to have seen this disease in New York City. In order to make the list complete we beg the privilege of reporting two undoubted cases occurring in native North Americans, seen in Kings County Hospital, Brooklyn, N. Y.

CASE I.—Mrs. A. B., aged 18, native of the United States; family history negative, except that one brother is a sailor; past history, had the usual diseases of childhood; no other illness; menstruation began at fifteen and had always been regular; no menstrual disorders. Personal history: Patient admits having had promiscuous sexual intercourse; shortly before her marriage she had intercourse with a South American sailor. She has been married three months; her husband is a Russian who has never been in the tropics and is, apparently, perfectly healthy; his Wassermann was negative. Present illness: About one month after her marriage and six weeks after her intercourse with the sailor, a small red papule developed on the left labia minora, which she scratched until it bled; following this a small wartlike growth appeared on the site of the papule; at first the color of the growth was pale pink, but as it grew larger the top became red and reddish brown; other papular wartlike growths appeared around the primary one and then the condition spread until it involved the entire vulva. Physical examination: The patient is a well developed and well nourished white female; the general physical examination, except for the growth on the vulva, is negative. Covering the external genitalia and extending for about one inch into the vagina is a bright red, ulcerating, papillomatous growth; the base and body of the growth is a pale, pinkish white; the top is bright red and ulcerating. The vaginal opening is almost closed and a small depression marks the site of the opening of the urethra; the outlines of the labia are lost in the folds of the growth; the entire growth is moist, although there is no urethral nor vaginal discharge; the odor from the mass is extremely foul; the inguinal glands on both sides are slightly enlarged. Urine analysis, negative; gonococcus and Wassermann, negative. The blood never was positive nor was there ever any cutaneous eruption. A section of the tumor was removed for examination. A tentative diagnosis of *tropical granuloma* was made, and the patient was put on the following treatment: Locally a one to one thousand solution of potassium permanganate as a douche, and internally gradually increasing doses of tartar emetic; shortly after she commenced treatment the condition began to improve, the moisture grew less, the foul odor disappeared, the ulceration began to heal and the tumor grew smaller; later the shrunken growth was removed surgically; the patient made an uninterrupted recovery and left the hospital apparently cured.

Laboratory report.—Several small pieces of tissue, vascular and of a papillomatous type, were excised from an extensive vulval growth; two of these were washed in several change of sterile saline solution, well macerated on a sterile plate and cultured in ascitic veal agar, both aerobically and anaerobically; the other pieces were placed in a four per cent. formalin solution for section. Smears made from the macerated tissue and stained by various methods showed the following bacteria: Unidentified Gram negative bacilli, staphylococci, unidentified Gram negative cocci, occasional acid-fast bacilli; occasional spirochetes resembling *S. refringens* and a short Gram positive bacilli; coccoid bacilli occurring in diplo-forms. All cultures showed a marked confluent viscid growth at the end of twenty-four hours, were of a dirty greyish white color, and possessed an odor peculiar to *Bacillus proteus*. Smears from the cultures showed Gram positive cocci (staphylococcus), Gram negative bacilli (proteus) and a Gram positive bacilli, short, almost coccoid, with no capsule. With Giemsa stain no capsules were ever demonstrated. Attempts at isolating the short Gram positive bacilli were unsuccessful. Subcultures were never pure.

Histological Examination.—Specimens showed a papillated structure; marked papillomatous hyperplasia of the epidermis and a granulomatosis of the derma, par-

*From the Department of Skin Diseases and Syphilis, Kings County Hospital, Brooklyn, N. Y.

ticularly of the pars papillaris. In general the stratum corneum is present and well preserved, except in some areas where ulceration has occurred, and the layer is replaced by a hemorrhagic and purulent exudate. The stratum granulosum is practically absent. The hyperplasia of the epidermis, already noted, is confined to the stratum mucosum, the component cells being swollen and, in a few instances, showing mitotic figures. The pars papillaris exhibits narrow and somewhat tortuous prolongations between the interpapillary processes of the epidermis. It is well vascularized and infiltrated with small round plasma and occasional polynuclear cells. The densest infiltration, however, occurs in the lower portion of the pars papillaris; here are found nests and aggregations of small polyblasts, including small round plasma and eosinophilic cells in close proximity to the blood vessels. In some areas these infiltrating cells are in perivascular positions, although not as typical as those encountered in luetic granuloma. The pars reticularis reveals interlacing fibrils of connective tissue, many of which are swollen or undergoing some degenerative change. In some areas there is new formed scar tissue.

Sections stained for bacteria show the presence of Gram positive cocci, short Gram positive coccoid bacilli, and occasional spirilla and spirochetes in the exudate from the ulcerated portions of the epidermis. No bacteria are demonstrated in the corium proper by any of the staining methods used, which included the Gram-Weigert, Thionin, Ziehl-Neilsen, Giemsa, and Levaditi.

Case II.—W. G., aged 29, Negro, born in the United States, was admitted to the Kings County Hospital, December 3, 1916. His personal history states that he had never been sick except for two attacks of fever, type or duration not known; had gonorrhea when he was twenty years old; had had an ulcerating sore on the foreskin six years ago, but had never noticed any cutaneous eruption. Knows nothing of the health history of parents or brothers and sisters. About a year before entering the hospital he noticed a "pimple" on the pubes, just above and slightly to the right of the penis; this papule gradually enlarged and ulcerated, the ulcer spread slowly until the pubes, inguinal regions, and the right side of the scrotum was involved.

Hospital History.—A well formed and well nourished negro; temperature normal; physical and urine examinations negative; complains of no pain, only a slight discomfort from the ulcerating area. In the groin, about the genitals, over the pubes, the right inguinal space, the right side of the scrotum, and the root of the penis, which is edematous and enlarged, there is a granulomatous ulcerating surface, pinkish white in color; the margins of the ulcer are nodular and gyrate in outline; there is also an ulcerating nodule about the size of a filbert on the foreskin; this was removed surgically; examination of the nodule for *Treponema pallida* was negative. Wassermann test with cholesterinized antigen, doubtful one plus. A tentative diagnosis of syphilis was made and he was given a provocative dose of arsphenamine; two days later the blood was three plus with cholesterinized antigen. On January, 17, 1917, he had an acute orchitis, which gradually subsided, leaving the testicle slightly enlarged. There was no urethral discharge and gonococci were never found. Between December 15, 1916, and February 23, 1917, he received eight full doses of arsphenamine and injections of salicylate of mercury in doses varying from one and one-half to two grains. After the last dose of the arsphenamine the urine showed evidences of kidney irritation and all medication was suspended for six weeks. The inguinal ulceration was first dressed with mercurial ointment; later this was changed to wet compresses of one to five thousand potassium permanganate. The center of the diseased area over the pubes began to heal, but the margins had slowly extended; the margins were curetted and cauterized with actual cautery. At first all of the diseased area seemed to be healing, but after a short time the scar broke down and ulcerated, especially at the borders. The blood was one plus doubtful on January 28, 1917, and negative two months later.

In June, 1918, a second course of arsphenamine was begun; six doses were given and the Wassermann that had been two plus became negative. The ulceration over the pubes was healed, but the lesion had extended over the perineum and along the inner surfaces of the thighs and over the penis. He left the hospital in November, 1918, and was readmitted in March, 1919, suffering from pneumonia which ran the usual course to recovery. The local lesion was about the same as when he left the hospital. After his recovery from pneumonia he received one dose of arsphenamine. A careful examination of the lesion at that time aroused the suspicion of tropical granuloma; antimony by the mouth was prescribed, but he left the hospital before the last remedy had had time to have any effect.

He was readmitted to the hospital August, 1919. The local lesion had extended over the perineum and over the opposing surfaces of the buttocks; except for a border the sixteenth of an inch wide the pubic lesion had healed into a thin white scar; the shaft of the penis was also scarred and the organ was enlarged—pseudo elephantiasis. He refused all treatment and left the hospital, but returned January, 1920. There was no marked change in the local lesion. During 1920 no systematic medication could be instituted because he was only intermittently in the hospital.

In June, 1921, he returned to the hospital and has remained there to date. The Wassermann was doubtful or negative, and has continued so ever since. The spinal fluid was always negative. The ulcerating borders were curetted and cauterized but failed to heal. He was then put upon antimony by mouth; the progress of the disease seems to be stayed and there are evidences of healing all over the lesion. Shortly after the patient entered the hospital the first time some of the tissue was examined microscopically.

Report—Subcutaneous tissue very dense, with areas of stratified squamous cells; the tissue is infiltrated with pus, lymphocytes, and plasma cells. Laboratory diagnosis: Syphilitic new growth.

Second Report, January, 1920.—Tissue from ulcerated lesion in groin; epidermis hyperplastic, of papillomatous character; true skin and subcutaneous tissue infiltrated with small and plasma cells and showing inflammatory changes. There were no cultures made at either of these examinations.

The last laboratory examination made in July, 1921, is as follows: Examination of tissue taken from an ulcerative lesion of the inguinal region. A portion was examined bacteriologically, the rest of the specimen was fixed in formalin for histological examination. Bacteriological examination: Direct smears from the specimen, stained by Gram's method, showed the following organisms: Gram positive diplococci, some of which, apparently, possess capsules; Gram negative coccoid bacilli. and staphylococci. Stained by Giemsa's method no spirochetes are demonstrated. Portions of the tissue were cultured both aerobically and anaerobically; examination of aerobic cultures by Gram's stain showed the predominance of staphylococci which gave varying reactions to the Gram method, some of them being positive and others (these in the majority) Gram negative; there were observed also a few Gram positive diplococci, a few short chain cocci, in general Gram negative in reaction, and many Gram positive spore-bearing bacilli. The Giemsa method of staining did not demonstrate capsule formation, and no spirochetes were observed. By the His method capsules were demonstrated. Anaerobic cultures showed a few isolated colonies within the substance of the medium; some of these colonies were fished out, smeared, and stained by the Gram method; the colonies showed the presence of Gram positive cocci, Gram negative cocci, and a few Gram negative coccoid bacilli which did not possess capsules.

Histopathological examination: Sections were stained by various methods, namely, routine hematoxylin-eosin method and by Giemsa, Gram-Weigert, Thionin, and Levaditi methods to demonstrate organisms. None of the latter methods disclosed the presence of any organisms within the derma; the Levaditi method was negative for spirochetes; the hematoxylin-eosin method showed the following pathological changes: The principal change observed in the epidermis consisted of a marked hyperplasia of the rete Malpighii; irregular tortuous prolongations extended downward into the pars papillaris of the derma. In the derma the following changes were observed: The pars papillaris showed moderate cellular infiltration, the cells being of the polyblastic type, and in areas replacement fibro-

sis had taken place; this layer was fairly well vascularized by small thin-walled capillaries; in the deeper portions of the pars papillaris, and particularly in the vicinity of the coil-gland ducts, were observed cellular infiltrations; the predominating type of cell was the plasma, although occasional eosinophiles and small round cells were encountered. The pars papillaris of the derma was somewhat edematous and consisted of interlacing fibers of connective tissue strands, many of which showed fraying; situated in the immediate vicinity of the blood vessels of this layer of the skin was likewise cellular infiltration, the type and character of cell being similar to that observed in the upper layer of the derma; no giant cells were seen nor were caseous areas in evidence.

Comparison of the clinical and microscopical findings in our cases and those of others is as follows: The best clinical description of the disease is, perhaps, that of Mansen (Tropical Medicine, Third Edition, p. 536). He says, "The disease commences, in the great majority of cases, in the groin as an insignificant, circumscribed, nodular thickening and elevation of the skin; the affected area being covered with a delicate, pinkish, easily rubbed off epithelium, excoriates readily, prone to bleed and break down, rarely ulcerating deeply. In its extension it exhibits a predilection for warm and moist surfaces, the fold between the scrotum and the thigh, the labia, and the flexures of the thighs. Its extension is slow.

Concurrently with peripheral extension a dense, contracting, uneven, readily broken down scar forms on the surface traveled over by the new growth, which constitutes the peripheral part of the diseased area.

In the male it may spread over the penis and involve the glands, the scrotum, and upper part of the thighs; in either sex it may spread to the pubes, over the perineum, and as far back as the coccyx.

The history and subsequent course of the disease in our cases closely conforms to Mansen's description, except that in the woman the growth at first was more papillomatous in character. Although, according to Pardo (*Journal of Cutaneous Diseases*, Vol. 4, p. 206), the papillomatous type has been observed by some. We were unable to cultivate the encapsulate bacilli described by Donovan (*Indian Medical Gazette*, xxxix, 414, 1905), but we did observe a Gram negative bacillus similar to that described by Flu (*Archives f. Schiffs u. Tropen Hygicne*, Beiheft 9, 1911). We also found Gram positive diploccoci; spirochetes of the refringens type were seen. Without carrying the comparison further we feel justified in considering both of our cases to be examples of tropical granuloma.

A Suspected Case.—Shortly after Case I had left the hospital a woman, aged 24, born in the United States, was admitted to the obstetrical division; she was eight months pregnant, first conception; upon examination an ulcerating tumor was found which involved nearly the entire vulva. She was transferred to our ward, where she was delivered of a healthy child at term. Clinically the vulvular growth resembled tropical granuloma, but the patient would not allow us to remove any of the growth for examination. Her Wassermann was always negative and she did not develop any eruption while in the hospital; we were unable to get a history of syphilis. She left the hospital at the end of her puerperal period, promising to return for treatment of the local lesion.

We agree with Campbell (*Journal of the American Medical Association*, Vol. lxxvi, No. 10, p. 64, 1921) that the disease is not uncommon in the United States, not endemic as in the tropics, but that it is being seen oftener and oftener here; perhaps the closer intermingling with the people from the West Indies may be a means of propagating the disease; there seem to be more cases occurring throughout the United States, especially in the large seaport cities, than the paucity of reports would lead one to suspect.

When a patient of the class in which this type of granuloma occurs presents himself or herself for treatment the diagnosis of syphilis is usually made without taking the pains to prove or disprove its correctness. Anyone who knows the clinical picture of syphilis should be able to differentiate this chronic and not especially troublesome new growth from the specific gummatous ulceration. The rapid spreading and painful ulceration of cancer is altogether different from the course of tropical granuloma. Tuberculosis of the genitalia is rare; one of us, after twenty-five years' experience, has seen only two undoubted cases out of a vast number of tumors and ulcerations of the genital regions. After a careful reading of the literature of ulcerating tumors of the pudenda we are led to believe that these granulomatous growths have often been seen, but not correctly diagnosed and, therefore, not reported.

In 1848 Huguier, in a brochure entitled "Memoire sur l'Esthiomene on Darte rongeaute de la Region Vulvo-anale," Paris, 1849, describes a number of ulcerating tumors of the female genitals, which he considered lupus. At least two of his cases, from the history of the onset and course of the lesion, might easily have been placed with the granulomas of non-syphilitic or tuberculous origin.

Dr. Isaac E. Taylor, in a paper read before the American Gynecological Society in 1880 (*Transactions American Gynccological Society*, Vol. 6, 1881), verifying Huguier's views of lupus of the female genitals, cites the histories of cases he has seen in New York that, from the clinical description, might easily have been examples of tropical granuloma.

In 1889 Robert W. Taylor, whose knowledge and perception of syphilis was unsurpassed, read a paper before the American Dermatological Association entitled "A Hitherto Undescribed Form of New Growth of the Vulva" (*American Journal of Medical Sciences*, Vol. xcix, p. 125, 1890), and in a subsequent paper (*New York Medical Journal*, Vol. 51, p. I, Jan. 4, 1890) describes a number of cases that had many features in common with what is now called tropical granuloma. The initial lesion was a soft nodule that broke down and ulcerated; the course of the ulceration was slow; all attempts at cure failed. Taylor did not consider these special growths to be either syphilitic or tuberculous, but believed them to be some unknown and hitherto undescribed form of new growth. The histopathology, as given in this article, is somewhat similar to that of the cases of tropical granuloma recently reported. Later Taylor concluded that he

had seen cases of so-called tropical granuloma in New York City.

After searching the literature and finding the references cited above we looked up the records from the syphilitic and skin ward of Kings County Hospital for the last twenty-five years. We found three histories of ulcerating granulomatous growths about the genitals, which bore a close resemblance to the disease under discussion. Two were women and one male; the man and one woman were negroes; all were natives of the United States and had never been in the tropics; they were from the underworld, the women were prostitutes, and the man a profligate with a criminal history. In each instance the onset and course of the disease was similar; the lesion began as a soft nodule situated in the vulva of the women and in the groin of the man; the nodule soon broke down and ulcerated; the ulceration extended until all of the vulva and perineum was involved. In the man the ulceration spread over both groins, extending to the scrotum and perineum; the center of the lesion tended to cicatrization, but the scar eventually broke down and ulcerated. A diagnosis of lues was made from a rather indefinite history of syphilitic infection; as these cases occurred before the discovery of either the spirochete or the Wassermann test, the diagnosis did not have the laboratory confirmation. One of the women died from inanition, the others left the hospital uncured and were lost sight of.

Summary.—As this disease occurs in different parts of the world, both in the temperate and torrid zones, it is safe to assume that it is not necessarily confined to the tropical and subtropical regions.

It is also probable that many cases of this disease have been seen by various physicians, but have not been recognized because the most natural diagnosis of new growths occurring in this part of the body would be syphilis or some other well-known ulcerating venereal disease.

As a great many of the observed cases had neither clinical nor sereological evidences of syphilis, it can be safely concluded that the disease is not caused by the *Treponema pallidum*, but by some other organism, in all probability the one that was discovered and described by Donovan.

Although the bacterial findings of various observers are not uniform, it can be assumed that the specific Donovan bodies were present in all cases, but owing to some faulty technique they were not always seen.

Antiluetic remedies have no effect upon the progress of the disease, neither has surgery alone ever made a permanent cure.

The only remedy that has any effect on the disease is antimony, given either by the mouth or, preferably, intravenously.

We wish to extend our thanks to Dr. Hala for his kindness in preparing the microscopical specimens and for the laboratory reports.

NOTE.—Since the above article was prepared Dr. Kenneth M. Lynch of Charleston, S. C., *The Journal of the American Medical Association* has published histories of nine cases observed in Charleston, and also comments upon a paper by Driscoll entitled "Erosive Vulvitis," published in the *Archives of Dermatology and Syphilis*, vol. 1, No. 170, February, 1920.

47 HALSEY STREET.

BORDERLINE ENDOCRINE CASES.

BY HENRY R. HARROWER, M.D., F.R.S.M. (LOND.).

GLENDALE, CALIF.

INFORMATION concerning the so-called "endocrine case" occupies considerable space in the books on the internal secretions, the newer systems of medicine, and a great many articles in current medical literature. The medical profession still holds the impression that the chief diseases definitely related to the ductless glands are myxedema, hyperthyroidism, acromegalia, Addison's disease, Froehlich's disease, tetany, and so on. These are the obvious endocrine diseases. They are the text-book conditions quite thoroughly studied, fairly easily diagnosed, and not so easily treated.

If endocrinology consisted in the study of these diseases and the development of knowledge regarding their treatment it would soon cease to be a new science and certainly would lose the interest that the medical profession has in it at the present time.

As a matter of fact, the study of this kind of endocrinology is not so very practical nor is it so especially profitable for two chief reasons: First, well-defined endocrine diseases are not really common, and, second, when they are discovered many of them are not very satisfactorily treated.

The class of disturbances of internal secretion which I have chosen to call "borderline endocrine cases," on the other hand, is a very comprehensive as well as an extensive class. It involves all of the functional conditions of varied origin into which the endocrine glands have been drawn as factors—causative and resultant; and in the study and treatment of which a knowledge of internal secretory physiology and relations and of organotherapeutic regulation opens a very much broader field of opportunity to the practising physician.

It seems that emphasis still is needed in order to remove from the minds of some physicians an erroneous impression that the study of endocrinology means the study of these decided, clear-cut, text-book endocrine diseases such as the ones mentioned in the first paragraph, and replacing it with an appreciation of the tremendous influence that the ductless glands play upon every reaction of the body to disease as well as the regulation of physiological functions which maintain health.

The borderline endocrine disorders are far the more numerous. They necessarily must include certain aspects of all of the acute infectious diseases, because the endocrine glands unquestionably are influenced by the conditions present in these diseases, and their undue stimulation causes functional disorder in the normal activities of these organs. The thyroid gland is expected to react to infections and toxemia, for the thyroid has been shown to be a very important factor in "the immunizing response of the body" and is known to be equally concerned in what is known as "the detoxicating mechanism." In other words, whenever there is an acute infectious disease consideration should be given to a possible thyroid aspect, and especially to the possible indirect influence upon the organism, either during the disease or following it, through a presumed derangement in the thyroid functioning.

There is also an equally important adrenal aspect to all such diseases because the adrenal glands, serving as they do to initiate the cardiovascular and sympathetic response of the body to infections and toxemias, necessarily must be stimulated by the toxic products of the infection or infectious disease. If the adrenal glands were not thus affected the body would speedily be overcome by the poisoning, but since the adrenals are immediately and subtly concerned in all of these syndromes, we find increased circulation, increased sympathetic tonicity, increased chemistry, and a general increase in the defensive activities of the body. Naturally, if the toxemia is a very serious one or, even more important, if it is not so serious but is prolonged over a long period of time, this constant stimulation of these glands doubtless will wear them out at least functionally, and as a result of the over-stimulation we have depletion.

Toxemias of other origin, including alimentary toxemia, the ingestion of toxin-containing foods (including coffee, easily putrefiable animal foods, and especially certain protein-bearing foods to which some individuals occasionally show an unusual susceptibility) exert an identical effect upon the endocrine glands, especially the thyroid and adrenals, as we expect to find from other forms of poisoning. Consequently, the frequency of endocrine dysfunction of the type under discussion is extended very materially indeed.

Still another very important aspect deserves brief mention. It has been shown both by physiological experiments and by clinical observation that emotional states are related to endocrine function, and that hyperemotivity, including the changes in the mental balance related to fear, rage, excitement, worry, and introspection exert an influence upon these selfsame glands. The French have even gone so far as to call the thyroid *"la glande de l'émotion,"* and Cannon and his associates definitely connected the adrenals with both the fear syndrome and the fatigue syndrome.

If, then, it is true that mental states such as have been referred to act upon the organism through certain of the glands of internal secretion, surely we have again extended very materially the number of disorders in which there is an endocrine factor worthy of consideration.

No mention has been made yet of the early but none the less important changes in endocrine activity based, perhaps, upon heredity, a changed cellular environment, or the chronic toxemia such as one expects to accompany either hereditary or acquired lues. Here circumstances have either changed some of the endocrine glands structurally or, at least, have burdened them unduly, have changed their duties or have played them out. In some instances, of course, these glands "have never had a chance" and fail to accomplish their intended duties, with the result that the individual unfortunate enough to have a dyscrinism of this character does not develop, and as a result is called a backward child, a defective child, or even an idiot.

The same fundamental principle applies in the relations that other functional endocrine disturbances bear to a long list of functional nervous diseases. The sympathetic nervous system in some way is connected with the endocrine glands. Some believe that the endocrine glands regulate the sympathetic mechanism directly; others contend that if the endocrine glands are not functioning normally, conditions are allowed to obtain in the body which cause an excessive stimulation of the sympathetic. In other words, the unoxidized poisons are permitted to remain in the organism, thereby unduly stimulating the sympathetics. No matter whether the relation of the endocrines to sympathetic disorders is one of cause to effect, or vice versa, there is, indeed, an undoubted relation, and, consequently, another large addition to the borderline endocrine cases must be the list of neurasthenias, neuroses, and psychoses in which there is sometimes no discernible connection between the disease itself and some previous cause. As a matter of fact, there is enough in the literature to-day to indicate that the most hopeful therapeutic aspect of many neuroses is the endocrine aspect, and a large number of physicians have come to believe that when they are confronted with a neurosis about which they can acquire no definite knowledge — when they are literally "stumped"—that sometimes the most reasonable thing to do is to begin to study the endocrine mechanism of the individual, to attempt to determine whether there is not some early and comparatively insignificant endocrine disturbance in order that it may be treated in the unscientific hope that the modification of this presumed dyscrinism may make some change for the better upon the complications, the relations and origin of which are so poorly understood. Without a doubt clinical experiences repeatedly have shown that all shades of nervous disorders, from plain, ordinary neurasthenia to insanity, are, or have been, related to the ductless glands and their functional derangement.

In some interesting correspondence with a physician who is devoting his entire time to mental and nervous troubles (he was formerly superintendent of a large State insane asylum) he makes the following interesting remarks:

"You don't have to prove to me at my age that I know more about insanity than some others. I am willing to admit it! But when it comes to those endocrines, I want to learn more. Let me say that for the last few years I have been using them. At first I was induced by the literature to use thyroid alone, and ovarian substance alone, or corpus luteum alone. Result: very little, if any, satisfaction. But since I have been using the pluriglandular formulas I have been running on high; in fact, am inclined to apply the brakes for fear my enthusiasm will run away with me. My results have been so much greater in treating neuroses and psychoses this way than by the old methods that I am inclined to be content, but when I get so much better speed than I ever did before, I realize that I have hit upon some new power, and now I want to develop it all I can, so am submitting a couple of cases to you for your judgment and whatever suggestions you feel will help. . . ."

This reminds me of another letter recently received from which I will quote a few paragraphs:

"My son has suffered from so-called dementia præcox for ten years. Why—the doctors do not

know. He has been at the ——— Clinic, at the ———, and to our two sanitariums here, one at ——— and the other at ———, where he still frequently stays. We have spent much money upon him, but without any improvement at all. Always a rather visionary child, he began by having hallucinations, to brood over life and death. It was all very gradual. Two years ago he began to have periods lasting sometimes for more than two weeks of absolute insanity. His mind went from him, though he always seemed to know a little, as though all the cells were not affected. Since taking the pituitary extract these spells have left him and he is at times almost normal. I do not expect impossibilities, but he seems to be growing better every day. Dr. ———, his present doctor, is dumfounded at the change in him. He has just passed his twenty-seventh birthday. Ten years given up to useless suffering both for him and me. I do not understand why doctors do not keep up with the times and try everything to make these poor creatures better. I write with a very full heart, and thank you over and over again for my little bit of hope."

The foregoing, from a physician's sister, encourages us to think of the large number of functional psychoses as being on the endocrine borderline.

Some years ago I made some remarks in a publication in regard to the frequency of ductless glandular disorders which aroused some criticism which I welcomed as a veiled compliment. I still meet individuals who contend that "Harrower sees a ductless glandular trouble in every case," and I confess that when I was in Paris ten years ago the same thing was said of Leopold Levi, for I recall very well the remark of a prominent physician who was talking with me about my hobby. He said, "Leopold Levi always considers every case that comes to him as one of dysthyroidism, and no matter whether they have rheumatism or sterility he can always prove that the thyroid is at fault." Now it *is* a matter of fact and it has been proved clinically many times that both rheumatism and sterility may, indeed, have a very decided thyroid aspect, and so when anybody says that those of us who choose to be on the firing line of practical endocrinology find the ductless glands involved in far too many conditions, and hint that there is an ulterior motive in our interest, we can show them from the literature and, better still, from our own clinical experiences which, by the way, are by no means limited in number or locality, *that the consideration of the endocrine aspects of any given case may, indeed, uncover a lead which will direct the physician in such a manner that he will have better control over the condition confronting him than in any other way.*

The borderline endocrine disorders, then, involve all those conditions of a toxic, bacterial, or emotional character in which the endocrine glands may be over-stimulated, thus causing their functional playing out or a compensatory over-activity on the part of organs which under normal circumstances are expected to cooperate with their related endocrine fellows.

Thus the borderline endocrine disorders are innumerable. Frankly, I have come to believe that practically all of the gamut of troubles which come to the average physician's office from day to day may have a sufficiently important endocrine aspect to warrant his giving special study to this phase of these cases, and whenever a suitable organotherapy reasonably may be directed at the presumed dyscrinism, the clinical results in a course of a few weeks may give us additional knowledge of diagnostic value which otherwise might never have been gained.

In other words, endocrinology is a much more comprehensive and practical science than some would lead us to believe, and organotherapy is of a very much more prospective value than its textbook therapeutic possibilities might indicate.

CALCIUM LACTOPHOSPHATE IN CYCLIC VOMITING.

By CRAWFORD R. GREEN, A.B., M.D.,

TROY, N. Y.

DURING the summer of 1919 I encountered a patient about fifty years of age who had been given calcium lactophosphate as part of the treatment for an obscure metabolic disorder. This patient had suffered from attacks of cyclic vomiting in childhood, and all her life since puberty she had suffered from severe attacks of migraine. When I first saw her she had been taking calcium lactophosphate for several months, during which time there had been a complete cessation of the attacks of migraine—a relief which she had not previously experienced for many years.

There seems to be an association between cyclic vomiting and migraine, and it is stated by most observers that the child who is a cyclic vomiter has the unhappy outlook of becoming a subject of migraine in adult life. At the time the patient who was taking calcium lactophosphate came under my observation, I was treating a particularly severe attack of cyclic vomiting in a boy eight years old, and I decided to give him calcium lactophosphate in the intervals between his attacks, reasoning that if there were a close association between the causation of cyclic vomiting and migraine there might be some similar correlation in their treatment.

This boy had first come under my care about one year previously at the age of seven, giving a history of having suffered from cyclic vomiting since the age of two. These attacks had occurred at intervals of one to three months, with a single exception of a period at the age of four when he did not have an attack for nine months. During the year he had been under my care, he had had attacks on an average of once in two months. These attacks lasted regularly for five days, during which time there was almost constant nausea and repeated vomiting of large quantities of bile. Absolutely nothing could be retained by mouth—no nourishment, no water, no medication. A competent nurse was employed at the onset of each attack to give salines and 5 per cent. dextrose by rectum. Every accepted method of treatment was tried without any effect whatever, and no relief was ever obtained until the attack had worn itself out on the fifth day. On two occasions the child was in such a seriously exhausted condition that we had a hard struggle to sustain life. In March, 1920, I began

the administration of calcium lactophosphate, two grains three times daily. This treatment has been continued without interruption to this date, September, 1921. There has been no attack since the beginning of treatment.

On September 16, 1920, a girl of eight was brought to me with a history of having had attacks of cyclic vomiting every month or two for the previous three years. These attacks each lasted about three days, and the condition had been diagnosed and treated by able physicians. No treatment had been of the slightest benefit. I prescribed calcium lactophosphate, two grains three times daily. The patient has reported regularly each month during the past year, and there has been no recurrence of the trouble.

At present I have two other severe typical cases under treatment with calcium lactophosphate, but sufficient time has not elapsed to warrant reporting them.

I am aware that two cases supply very meager material from which to draw conclusions regarding any therapeutic procedure, but I feel that even a suggestion toward the relief of such an intractable and distressing condition is well worth consideration. I am therefore recording these two cases merely with the hope that they may excite the interest of someone who is in touch with sufficient clinical material to prove or disprove the value of the remedy.

1 am further encouraged in the possibilities of success with calcium lactophosphate by the fact that a few adult victims of migraine for whom I have prescribed calcium lactophosphate, five grains three times daily, taken over a considerable period, have received marked relief. Calcium, usually in the form of the lactate, is not uncommonly employed for the relief of recurrent headaches in individuals of the so-called lymphatic type; but the cases to which I refer, in which I have successfully used the lactophosphate are cases of periodic attacks of "sick headache," or migraine of the severe type that ordinarily resists every attempt toward permanent relief.

UNEXPLAINED CONSTITUTIONAL SYMPTOMS CAUSED BY FOREIGN BODY IN THE TISSUES.

By MAX J. SCHROEDER, M.D.,

NEW YORK.

THE facts in the case to be presented illustrate the necessity of a complete physical examination. They also emphasize the elusiveness of foreign bodies.

History.—C. K. when 15 months old playing around a tray suddenly let out a yell, was strangling, and grew cyanotic. The mother ran to her rescue, looked into the child's mouth just in time to see some safety-pins disappearing. In the struggle to remove them she pushed them in still further. After a few seconds the child regained its breath. The mother immediately took the child to one of the leading hospitals of the city of New York.

I have recently personally investigated the history and physical examination of the child when at the hospital and found that the child stayed there about 5 days during which time various *x*-ray plates of the gastrointestinal tract were taken. The authorities arriving at no diagnosis, the child was discharged.

It was from that time that the child who was always in a rosy and pink condition, began to develop a very obnoxious odor in the breath, had a poor appetite, and enjoyed very little sleep. This condition resulted in a retardation of development and growth. The mother had the child examined by various physicians, giving the full history; but none of them arrived at any definite diagnosis, assuring the mother if the child had ever swallowed any safety-pins they must be out long ago.

About 14 months after the safety-pins had been swallowed, C. K. took sick, the doctor in charge pronounced the case to be one of anterior poliomyelitis.

Physical Examination.—It was on the 30th of August, 1920, that C. K., then being almost 3 years old, for the first time came under my care. I examined the child and was impressed by the emaciation, very repulsive breath; the temperature when taken per rectum was found to be 103.5°; pulse, 130; heart and lungs were negative. Examining the oral cavity my attention was immediately arrested by a slight elevation of the posterior wall of the pharynx a little above the natural position of the soft palate. Upon closer scrutiny, I could see a glistening body. After due aseptic precautions, I incised this elevation and was amazed to withdraw 3 medium sized safety-pins, rusty and greenish looking, followed by a gush of thick pus.

After ordinary attention and care to this cavity for about 3 weeks, it completely closed. The child was beginning to lose the nasty odor from its breath, gaining weight, sleeping better, and turning brighter. Today the child looks like any average girl of her age.

Comments.—1. The primary landing of the safety-pins is conjectural; it is permissible to assume that they first landed in the stomach but the child later vomited them up. 2. In the course of vomiting they were halted in the pharynx, where they lodged. 3. In the event that foreign bodies have been swallowed it emphasizes the necessity to *x*-ray the head as well as the gastrointestinal tract. 4. It is plausible to believe that the anterior poliomyelitis arose from the contiguity of infection.

416 East Sixth Street.

Medicolegal Notes.

In Action to Compel Board of Examiners to Approve Medical School, Evidence as to Course of Instruction Is Admissible.—In an action brought in accordance with section 10½ of the California Medical Practice Act, to compel the State Board of Medical Examiners to approve the plaintiff as a school whose graduates are entitled to examination before the board of physician and surgeon certificates, and to admit the graduates thereof to examination for those certificates, it is held that evidence as to the quality of the course of instruction is admissible as bearing on the question of whether the school had complied with the requirements of section 10, and its exclusion would be reversible error, section 10½ allowing the board to consider the quality of the course of instruction.—College of Osteopathic Physicians and Surgeons of Los Angeles v. Board of Medical Examiners (Cal.) 199 Pac. 1093.

Inference of Negligence Not to Be Inferred from X-Ray Burn Alone.—In an action against a physician for injuries caused by an *x*-ray machine used in the treatment of disease of the skin, where the question was as to the safety of the machine, and not as to its efficiency, and there was no testimony that it was not safe when properly used, but, on the contrary, all the experts testified that it was all right, so far as safety was concerned, when used with proper safety devices, the defendant was not required to submit to the jury any issue involved in the exercise of care and knowledge in the selection of a machine. It was also held that in the absence of evidence from which, without speculating, the jury could draw a reasonable inference from the mere fact that the patient was burned by the rays from the machine, the jury should not be permitted to infer negligence from the occurrence alone.—Street v. Hodgson, Maryland Court of Appeals, 115 Atl. 27.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, January 14, 1922.

REPORT OF THE SURGEON GENERAL OF THE UNITED STATES NAVY.

THE vanishing lure of the sea has continued to cause difficulty to the Bureau of Medicine and Surgery of the United States Navy during the fiscal year ending June 30, 1921, the activities of which are recorded by the Surgeon General in his annual report to the Secretary of the Navy. We noted this same difficulty in the report for 1920. Despite the added educational and other advantages offered, the department has experienced difficulty in securing acquisitions to the commissioned personnel, as well as to the Nurse Corps and Hospital Corps. The especially enticing opportunities in civil life which present themselves to recent graduates of medical, dental, and pharmaceutical colleges and of training schools for nurses, are offered as the explanation of this state of affairs. Not only does the Navy not interest the recent graduates, it seems, but even the regular service appears to be attracted by the glitter of civil life gold, professional prospects, or what not. At any rate, since the signing of the armistice there have been 268 resignations from medical officers in the regular service, 46 of which occurred during the fiscal year covered by the report. Perhaps, with too keen foresight, these seafaring doctors visualized a ship scrapping melee and merely observed the adage which calls discretion the better part of valor. The commissioned medical personnel on duty July 1, 1921, comprised 768 medical officers of the Navy, 71 of temporary appointment, 47 of the Naval Reserve Force, and 71 pharmacists serving under temporary appointment as lieutenants in the Medical Corps of the Navy, making a total of 935.

During the past year the Bureau of Medicine and Surgery has aimed to increase educational advantages available to medical officers who have long displayed ability and earnestness in their profession, as well as to those who have entered the Medical Corps of the Navy since the beginning of the war. With this in view, a close relationship between the bureau and the Naval Medical School has been established to carry out certain policies of education. The bureau, we are told, has modified the curriculum at the school so as to strengthen the department of naval hygiene, which, in the future, will lay more emphasis upon branches of naval hygiene which have been an outgrowth of the war. Notable among these are the hygiene of gas defense, submarine warfare, and aviation, especially those factors which apply to flying in high altitudes. With the provision for courses at the Naval Medical School, special medical study at civilian medical clinics, and surgical study at the Mayo Foundation, at Washington University, St. Louis, and at the Massachusetts General Hospital, it would seem that the Bureau of Medicine and Surgery has been amply generous along the line of educational opportunities for its medical personnel.

In a recent editorial review of the Annual Report of the Surgeon General of the Army attention was directed to the item headed "Unsatisfactory Character of Recruits." It appears that the same state of affairs exists in the Navy, for the Surgeon General tells us that in order to recruit the Navy to its full quota, men of inferior physical and oftentimes of doubtful mental capacity were accepted. Such men, as a result of change in environment and of living under military discipline, are poor risks from the standpoint of the health of the Navy. Men of poor physique soon become fatigued by their active military training, and men of poor mentality never learn to care for themselves properly. The extreme youth of the newly enlisted personnel is also noted in the Naval recruits, and the fact that many were from rural districts. The young adults, many of whom were mere boys, had never been away from home influences, and consequently knew little about personal hygiene. This could not be taught in the short interval they were at training station. The boys from the rural districts in most instances had never been exposed to the various communicable diseases common to childhood. Consequently, as soon as mumps, measles, and other communicable diseases appeared at a training station, these "raw recruits" furnished fertile ground for their propagation. The increased incidence of communicable diseases in the Navy in November and December, 1920, was due, therefore, not to any neglect in the use of preventive measures, but to the rapid expansion preceding the outbreak, and to the calibre of the recruits. For, according to the Surgeon General, had the recruits enlisted during the past year been of proper physical and mental calibre, it is believed that the rates for communicable diseases would not have reached such a high peak in the winter of 1920 and 1921. The admission rate for all causes, entire Navy, was 778.99 per 1,000, as compared with 676.02 per 1,000 for the calendar year of 1919, and a mean rate of 463.80 for the five-year period immediately preceding the war. This high rate is attributed to influenza and the induction of large numbers of men into the Navy during the last five months of the year. It will be interesting to see if there will be any effect upon morbidity rates for the present year induced by or in consequence of the training and regime to which the large number of low calibre recruits will have been subjected in the meantime.

DISLOCATION OF THE SHOULDER WITH FRACTURE OF THE SURGICAL NECK OF THE HUMERUS.

In this double lesion many of the symptoms of simple dislocation of the shoulder and simple fracture of the upper end of the humerus will be combined. The principal symptom of shoulder dislocation is the absence of the head of the humerus from the glenoid cavity and, as a corollary, its situation near by. As in simple dislocation, the sign of the epaulet is present, but the humeral insertion of the deltoid is perhaps not so protruding because the axis of the limb is not greatly deviated unless the fragments of the fracture are impacted. The concomitant signs of fracture are the nontransmission of movements imparted to the arm, the ease with which the limb can sometimes be moved, but above all bone crepitation. The latter sign will not exist when the fragments are far apart or when there is impaction, both of which are infrequent. Instead of abduction found in simple dislocation the arm may lie near the trunk, and another symptom is that the movements of rotation of the arm are not painful to any extent in simple dislocation, while when fracture exists the pain is severe. There is almost always shortening of the limb varying from a half to one inch. Finally, when the arm is seized at the shoulder and the limb raised in the direction of its axis a movement of ascension can be imparted to it that cannot be produced in cases of simple dislocation.

Besides these special symptoms there are the general symptoms of dislocations and fractures, namely, ecchymosis, swelling, and functional impotence. Here, as in simple dislocation, there is paralysis of the deltoid, undoubtedly due to contusion or stretching of the circumflex nerve. This paralysis usually retrogresses unless the reaction of degeneration is present which proves that the nerve has been involved in its vitality. Lesions of the brachial plexus are rare so that disturbances of mobility and sensibility in the corresponding area are exceptional. However, the patient may sometimes complain of severe pain at the lower third of the radial side of the forearm when the arm is moved, this pain being perhaps due to compression of the radial nerve by the callus.

Complications are infrequent in shoulder dislocations complicated with fracture of the humerus. Wounds of the integument are rare. Some instances of vascular lesions have been reported. In one case the axillary artery was run through by a fragment of bone, and in two reported instances there was compression of the vessels and rupture of the internal and middle tunics with stretching of the adventitia. These lesions were made manifest by absence of pulsation in the radial and brachial arteries, as well as by coldness of the limb. Lesions of the nerves are still more uncommon and we know of no case in which the radial nerve has been comprised in the callus as occasionally occurs in simple fracture of the humerus. A complication that is to be feared and should be avoided is stiffness of the joint, because the scapulohumeral articulation becomes quickly ankylosed and destroyed, as Malgaigne long since pointed out. Therefore, early mobilization should be the basis of treatment of these cases.

The evolution of the injury will depend upon the extent of the lesions and the surgical treatment employed. When left alone there is but one result, namely, ankylosis. The prognosis from the viewpoint of function is always serious, because the arm will never recover absolute integrity of its movements. But if mobilization, massage, and electricity are resorted to within a week or ten days after the injury has been received, the patient will at the end of three or four weeks be able to put the hand of the injured arm on the opposite shoulder or on his back, a result not obtained for several months when other treatments are adopted. Abduction is the movement most slowly recovered.

PHYSICIANS AS VOCATIONAL EXPERTS.

The professed vocational experts have not as far as we know been men of medical training. Occasionally medical men have good opportunities for dissuading individuals from taking up this or that career, or to order change of occupation, but constructive efforts along this line do not seem to be in their province. The pedagogue and psychologist have superior opportunities in this direction, and the child who excels in penmanship, drawing, and music is pretty sure to have his future determined largely by these talents. In an article by Soucek, a pediatrist of Vienna (*Wiener klinische Wochenschrift*, December 1, 1921, xxxiv, 48) the author claims that the function of the physician is properly directed against unwise choice of an occupation for which the youth may be properly qualified mentally, but disqualified physically. Heredity is a very important factor for certain occupations run in families; but a study of history and biography shows us how frequently it happens that a man is disqualified physically from following the family vocation. It does not require expert knowledge to dissuade the candidate for tuberculosis from following a bureaucratic career. Very blond men are apt to do badly in occupations which necessitate much exposure to the sun, as gardening and horticulture. The author mentions a case in which a man who was unsuited for gardening made matters worse by working as a stoker; for those sensitive to solar rays are also sensitive to heat in general. Polar explorers are said to be afraid of blonds, who are no less sensitive to extreme cold than extreme heat.

The ophthalmologist should have a voice in vocational advice, for poor vision disqualifies in a great variety of occupations. But he functions as a consultant and we believe is seldom sought as a principal. It is certain that he could often drop a hint to a young man that he should not follow certain occupations, as for example that of jeweler. However, it is not uncommon for young men with

severe astigmatism to waste much time in occupations which they must finally give up because those who might have warned them neglected to do so. The myopic man is at home in clerical positions. Skeletal deformities are often aggravated by certain occupations. The waiter with flat feet becomes worse from his occupation, as does the baker or cabinet maker with knock knees; clearly these men should have elected callings which might have antagonized their deformities. Medical examination of high school graduates who are to go to work will give many vocational hints. Some boys of 15 are unfit for labor of any kind, and should attempt nothing for another year or so. This incapacity may be due to transitory slight deformities, fainting attacks, etc., which will soon be outgrown.

Sousek believes that eventually the medical man will pass to more constructive vocational advice and tell the young not only what they are unfit for but the kinds of work for which they are especially adapted. A course with this scope might be placed in the postgraduate medical college curriculum through which the practitioner could become qualified to cooperate with parents and teachers in choosing a career for the adolescent.

THE "NEW DOCTRINE" OF ORAL (DENTAL) SEPSIS.

Readers of foreign medical literature have for years marvelled at the silence and indifference of the profession on the Continent of Europe concerning the American teaching regarding buccodental sepsis. When a case of oral sepsis does appear in one of the European medical periodicals the chances are that it is genuine acute septicemia of the fulminant type. French stomatologists have pointed out that some of their own men long ago put cases on record which correspond to the American type of a slow, relatively mild sepsis or toxemia expressed as pseudorheumatism, etc. It has even been claimed that some of these reports antedate the earliest observations in the United States. This is very likely correct, but it is also correct to assert that such cases passed unnoted. A puzzling feature was the superiority of American over European dentistry or perhaps it would be better to speak of the superiority of the viewpoint of the average American citizen who keeps his teeth in repair when the same caste in Europe simply have their teeth extracted as fast as they decay. This almost suggested that dental sepsis was a creation of modern conservative dentistry. The wholesale extraction of recent years in the United States, since the propaganda of dental infection, seems in part to strengthen this view.

In the *Wiener klinische Wochenschrift* for November 24, 1921, xxxiv, 47, is an abstract of a paper by Kornfeld entitled "The New Doctrine of Dental Infection of the Organism" which shows that the subject has at last attracted the serious attention of clinicians of Middle Europe. Credit of priority is given to the Mayo brothers and Osler, or perhaps the genuineness of the affection is guaranteed by these names, the owners of which pointed out the extreme importance of the subject in the prophylaxis of disease. It must of course be remembered that Vienna was cut off from American medical literature for nearly five years. Kornfeld quotes from a work termed the "Atlas of Life" from which he evidently obtained his data.

This work is said to have appeared in 1920 in English and is of encyclopedic character; and in its columns the speaker had found a wealth of information on focal infection which seems to have been largely new to him. He is fully convinced that the profession in Austria must awaken to the importance of the subject—that caries must be prevented by all means both before and after the appearance of small cavities; that the *x*-ray plate is the key to the situation; that there must be a more thorough removal of dead roots and pulpless teeth, and at the same time better conservative dentistry effecting sterilization of teeth and roots not extracted. The speaker is himself a dentist who gives his message to the Vienna Medical Society.

Bacteriemic Erythema Nodosum.

In the Medical Record for December 17, 1921, was an editorial note in which it was stated that this affection is regarded by Damiéville of Lausanne as *sui generis* and not secondary to tuberculosis or any other general infection. The material on which this opinion was based was of the polyclinic type. But in the *Bulletin Médical* for December 3, 1921, xxxv, 49, Saquépée relates a case of pneumococcus septicemia in the course of which the patient developed both herpes zoster and erythema nodosum, the latter typical in appearance. He recalls that in 1905 Loiseleur saw erythema nodosum complicate a streptococcus sepsis. There were no prodromes, for, of course, such could not have been recognized in the presence of septicemia. Tuberculosis could be excluded. The septicemia was not of a high degree and there was no lesion of the lung, which is very unusual in this form of sepsis. The reader obtains the impression that these dermatoses were due directly to the parasitism of the pneumococcus. The latter, which was recovered from the blood in pure culture, was of the variety known as pneumococcus Type I. The case in question recalls an old view that this dermatosis was the result of a low form of rheumatoidal sepsis and could be accompanied by endocarditis. This rheumatic theory seems to have been supplanted by the view that the underlying process is tuberculous. At the present time therefore we seem to know less than ever about the malady which has recently been pronounced an infection *sui generis* as above stated.

News of the Week.

Typhus Epidemic in Russia.—According to a special cablegram from Moscow to the *New York Times*, under date of January 5, typhus fever is being spread by refugees from the famine area and is assuming epidemic proportions. Upwards of 800 cases were reported to the hospitals of Mos-

cow during the week ending December 17. The report states that unquestionably the total number of cases is far greater than is notified, for the press contains urgent appeals to the people not to conceal cases of sickness. Efforts are being made to fight the plague by division of the city into sections supervised by the Health Department and controlled by members of the Moscow Soviet; by wide distribution of free bathhouse tickets, and an appeal to Communists to help scavenging, which is inadequate. The railroad stations are the worst source of contagion and thus far nothing has been done in the way of a delousing scheme at the stations and in all buildings where the disease occurs, which alone would be really effective. Relief workers believe that 5,000,000 deaths in the famine area is a low estimate, and that 10,000,000 human beings may perish as a result of the famine and pestilence. Typhus is so prevalent through the Volga region and in Turkestan that the Soviet Government has stopped all passenger service to and from those regions.

Infant Death Rate in Big Cities.—Figures recently issued by the Registrar-General of Great Britain show a surprising disparity in the death rate of babies in different cities of the world. Christiania during the last quarter of 1921 had the best record; the death rate among babies under one year was thirty-three in every thousand. In Amsterdam the rate was forty-two, in Stockholm forty-eight and in London ninety-three. Bombay had the worst record, with 630 deaths out of every thousand.

Proposal to Disenroll the Medical Reserve Corps of the United States Public Health Service.—The plan recommended by Walter F. Brown, Chairman of the Joint Committee on Reorganization of the Administrative Branch of the Government, to disenroll the reserve corps of medical officers of the United States Public Health Service is meeting with vigorous protests. The American Legion and other veteran organizations disapprove of the plan. Surgeon-General Cumming has stated that he thinks the proposed reorganization would demoralize the corps and be a serious detriment to the ex-service men in the hospitals. Surgeon-General Stitt of the Navy and Surgeon-General Ireland of the Army are likewise opposed to the plan. Reducing the 1200 reserve medical officers of the Public Health Service to a civilian status, it is claimed, would result in a saving to the Government of about $750,000 a year. Brigadier-General Sawyer, President Harding's personal physician, is said to favor the plan. About 97 per cent. of the surgeons now working in the Public Health Hospitals are former army surgeons who have seen service in France. Many of these are specialists who have given up lucrative practices to develop for the Government the best in tuberculosis and other special treatments. These men would be affected by the order, should the President issue it.

Philippine Public Health Work Aided by Rockefeller Foundation.—The International Board of the Rockefeller Foundation has accepted an invitation to cooperate in carrying out the general scheme of reorganization of the public health activities of the Philippine Islands, which was recently made public by the President of the Senate, Manuel Quezon. The participation of the Board will consist in lending the services of certain members of its staff for a limited period and providing specialists as consultants and assistants to Philippine Government officials in various lines of public health work. The broad program which the Government has adopted for improving health conditions includes the ultimate consolidation of all health functions in a single department of health to correspond with the ministry of health in other countries. Among the persons whose services will be furnished by the Rockefeller Foundation is an assistant to the dean of the College of Medicine and Surgery of the University of the Philippines, who will assist in developing the medical school and will give particular attention to the problem of providing post-graduate instruction in public health so that the health workers so urgently needed in the Philippine Islands may be trained locally. Fellowships for advanced study in the United States will be offered by the Board to exceptionally promising and well qualified young Filipinos. The nursing situation will also be studied and special attention will be given to training women in public health nursing. Dr. Victor G. Heiser, Director for the East of the International Health Board, and formerly Director of Health for the Philippine Islands, will go to Manila in February to assist in carrying out the program.

Internationalizing Sera Standards.—Cooperation of the foremost laboratories of the world for the unification of international standards of antitoxic sera has been begun by the League of Nations Health Committee. Two preparatory conferences have been held, the work has been divided amongst the various national laboratories, and the individual studies have been begun. The United States has agreed to cooperate in this work through the United States Public Health Service at Washington, and through the presence at the conferences of Dr. Rupert Blue, Assistant Surgeon General, stationed at Paris.

Use of Drugs Not Due to Dry Law.—The statement that prohibition has resulted in an increase in the number of drug addicts in the country has been denied by Colonel O. G. Forrer, administrative assistant in the Narcotic Division of the Treasury Department, who says that victims of the drug habit practically in every instance are young men and women, often in their teens. Rarely are they alcoholics.

Prescriptions for Alcohol.—According to the records of prohibition agents, physicians in the Chicago district issued 2,189,000 liquor prescriptions in 1921. The figures for New York State, made public by Ralph A. Day, Federal Prohibition Director, show that during 1921, there were issued in this State a total of 946,700 liquor prescriptions by practising physicians. There are 12,500 physicians in the State; therefore the average number of prescriptions for each physician is seventy-six, which is considered small.

Alcoholism at Bellevue Hospital.—Dr. Menas S. Gregory, director of the psychopathic and alcoholic service of Bellevue Hospital, has given out figures showing that 2,381 cases of alcoholism were admitted to Bellevue Hospital in 1921, as compared with 2,091 for 1920. In 1914, the total number of cases admitted was 7,642, and in 1916, 9,293. The large majority of the cases treated in Bellevue during the

past two years were men and women who previously were not considered inebriates. Dr. Gregory states that no comparison can be made between the condition of the patients in the enforcement period and the preprohibition period. Formerly when good whisky was available persons could easily be relieved of their sufferings in a short time. Now they face serious and perhaps permanent ailments from overindulgence. Dr. Gregory advocates lawfully regulated beer and light wine as a possible solution of the problem and emphasizes very strongly that inebriety cannot be overcome simply by withholding the alcohol. It can only be destroyed by being replaced; the intoxication motive must find another outlet.

Cause of Some of the Deaths Attributed to Wood Alcohol.—During the past two weeks there have been a number of deaths in New York City which have been attributed to wood alcohol. From a commercial source comes the statement that these deaths are probably due not to liquor containing wood alcohol but to that concocted of preparations which are intended for toilet use. These preparations are legalized formulae containing acetone and isopropyl alcohol, and can be obtained without permit. Purchasers of these compounds having a knowledge of chemistry recover the ethyl alcohol they contain, but the majority of buyers simply color the preparations and sell them for whiskey. Antidotes for wood alcohol do not combat either of these chemicals, according to the expert chemist who calls attention to the use of these preparations as beverages.

Automobile Deaths in the United States in 1921.—According to the National Highways Protective Society, 1,981 persons were killed by automobile trucks and passenger cars in New York State, including New York City, in 1921. This is the highest number of motor fatalities ever recorded in the State. The fatalities in 1921 were 452 more than in 1920. In the City of New York automobiles caused the death of 835 persons, 281 of whom were killed by trucks. The increase of automobile fatalities since 1919 in the State of New York was nearly 60 per cent. In 1919 the number of deaths was 1,270. The report of the society shows that in December last 185 persons met death by automobiles in the whole State.

Constitutionality of Willis-Campbell Law Attacked.—In arguing recently before Judge Edwin L. Garvin, in the Federal Court in Brooklyn an application for an injunction to restrain the Federal prohibition authorities from interfering with the manufacture and permit-sale of beer for medicinal purposes, Mr. William M. K. Olcott attacked the constitutionality of the Willis-Campbell law for the following reasons: (1) It is an invasion of the personal rights of a physician to prescribe and for a patient to use what the former in his knowledge and experience has deemed best as a health giving prescription. (2) It interferes with human rights because it destroys the right of breweries to cooperate with physicians, druggists, and patients in the sale of liquor for medicinal purposes, a use never prohibited by the Eighteenth Amendment. (3) Because the attempt of Congress to make such enactments is not within its powers as contravening that portion of the Constitution which limits to Congress the express powers delegated to it and expressly reserved to the State those powers not delegated. (4) On the broad ground that it is an attempt on the part of Congress to usurp the police powers never given to it by the Constitution or any of its amendments—a power clearly reserved to the individual States and which have always been considered the exclusive rights of the State. Mr. Olcott said further that Congress was not in a position to judge that medicinal-beer would make the brewers, the druggists, and the sick all law-breakers, he said. Congress had permitted the sale of cocaine and other habit-forming drugs on the prescription of a physician, therefore, why not beer? The Assistant United States District Attorney stated the Government's position. Judge Garvin is holding the matter under advisement.

Two Bills Demand Federal Inquiry Into Narcotic Drug Situation.—Representative Lester D. Volk of New York has introduced two resolutions in Congress dealing with narcotic drug addiction in the United States. One resolution directs the Secretary of the Treasury to furnish facts concerning a recent ruling of the Internal Revenue Department which would deprive addicts of the treatment and advice of their physicians and compel them to enter penal institutions and private sanatoriums for treatment. The other calls for an investigation of the entire subject of drug addiction, the method of handling addicts, and for the purpose of drafting legislation for the control of narcotic drug addiction. Congressman Volk says he has been led to introduce these resolutions largely because of the situation in regard to narcotic drug addiction in New York, which he characterizes as a national disgrace.

Hospital Notes.—A movement to enlarge the Reconstruction Hospital, 100th Street and Central Park West, New York, and develop it into one of the finest institutions for post-operative treatment in the country, was launched at a meeting of the directors on January 5. Plans were formulated to raise $1,500,000 to build a twelve-story hospital building for the treatment of industrial accidents and diseases. The Reconstruction Hospital was incorporated on February 19, 1921, through a consolidation of the Clinic for Functional Re-education, opened on July 15, 1918, for war injured, together with a number of industrial casualties, both of which have been treated from the beginning by new methods of operation and particularly after-care learned in the war; the Demilt Dispensary, founded in 1851; the Park Hospital, founded in 1902, and the Institute for Crippled and Disabled Men. Since the opening of the institution, 206,146 treatments have been given to 3,555 patients. At first the cases were practically 100 per cent. from the Government. Government cases have now fallen to 25 per cent. and industrial cases have increased to 75 per cent. of the total. Dr. W. Gilman Thompson is head of the institution.

The Sydenham Post-Graduate Hospital, on East 116th Street, has purchased the block front on the west side of Manhattan Avenue from West 123d Street to 124th Street and extending through to Hancock Place, upon which it plans to erect a ten-story fireproof hospital building. The cost of the new building, including the site and equipment, is

estimated at $1,000,000. One of the features of the institution will be the elimination of wards, as every patient, whether free or contributing, will have a sperate room.

A new hospital has been established in North Hudson and is known as the Physicians' and Surgeons' Hospital of West Hoboken. The institution will be incorporated at $10,000 and will have a capacity of ten beds at first. This number will be increased to twenty-four very soon.

A contract for additions to the Boston City Hospital totalling $493,000 have been awarded. Under the proposed plan the capacity of the out-patient department will be increased from 500 to 1000. Two additional stories will be added to the building, and each end of the building will be lengthened by forty feet.

Dr. Virgil P. Gibney was presented with a loving cup on the occasion of his fiftieth anniversary as head of the Hospital for Ruptured and Crippled, New York. The cup is engraved with the following lines: "1871-1921, Dr. Virgil P. Gibney, who for half a century has devoted his faithful services and masterful ability to the advancement and guidance of the New York Society for the Relief of the Ruptured and Crippled. Presented by the Trustees and Staff of the New York Society for the Relief of the Ruptured and Crippled." A record of the work done by the hospital has been compiled in connection with the celebration of the fiftieth anniversary of Dr. Gibney's service to the institution which shows that 503,403 patients have been treated during this period.

Dr. H. M. Robertson has removed his offices to suites 211 and 212 in the new medical building, North Main Street, between Sixth and Seventh streets, Santa Ana, Cal.

Dr. S. Pope Brown has been appointed village health officer of Potsdam, N. Y., to succeed Dr. Frank J. Fuller, who still retains the office of town health officer.

Dr. Joseph P. Londrigan has been appointed president of the staff of St. Mary's Hospital, Hoboken, N. J.

Charitable Bequests.—The will of Morris S. Barnet makes the following bequests: Mount Sinai Hospital, New York, $50,000; United Hebrew Charities and Montefiore Home, each $2,000, and Beth Israel Hospital and the National Jewish Home for Consumptives, Denver, Colo., each $500.

Roosevelt Hospital, New York, is the recipient of more than $400,000 under the will of Miss Helen T. Cole.

Obituary Notes.—Dr. GEORGE E. SHOEMAKER of Philadelphia, a graduate of the University of Pennsylvania School of Medicine in 1882, died on December 6, at the age of sixty-four years. He was a member of the Philadelphia County Medical Society, the Medical Society of the State of Pennsylvania, the Philadelphia Academy of Surgery, the Obstetrical Society of Philadelphia, the Philadelphia College of Physicians, the American Medical Association and the American College of Surgeons.

Dr. BYRON B. POTTER, a graduate of the Cincinnati College of Medicine and Surgery in 1869, and a Civil War veteran, died suddenly at his home in Lancaster, Mo., on December 16, at the age of seventy-four years.

Dr. DAVID HAROLD of Indianapolis, a graduate of the Physio-Medical College of Indian in 1889, died on November 30, at the age of seventy-seven years.

Dr. CHARLES HUTCHINSON, a retired physician of Portland, Me., died on December 5, at the age of ninety years. He was graduated from the Albany Medical College and served as a civilian physician in the Civil War.

Dr. JOHN J. RHEINHART of St. Louis, Mo., a graduate of Barnes Medical College, St. Louis, died suddenly on December 8, at the age of forty-four years.

Dr. MALCOLM MACFARLAN, formerly professor of surgery at the Hahnemann Hospital, Philadelphia, died at Ardmore, Pa., on December 9, at the age of eighty years. He was graduated from Yale Medical School in 1865 and served as field surgeon during the Civil War.

Obituary.

JOSEPH MacDONALD, JR., M. D.

NEW YORK.

DR. JOSEPH MACDONALD, Jr., died suddenly of apoplexy on January 7, at his home in East Orange, N. J. He was born in Branchville, N. J., in 1870, and was graduated from the Medical Department of the University of Baltimore in 1904. He was connected for a time with the *International Journal of Surgery*, and in 1905 founded the *American Journal of Surgery* of which he was managing editor. He was a prominent Mason, being Past Grand Commander of the Knights Templar of New Jersey. During the war he served as Major in the Medical Corps of the U. S. Army, being actively engaged in securing volunteers for the medical service.

Dr. MacDonald was a member of the Medical Society of New Jersey, of the American Medical Association, and of the American Medical Editors' Association. He was for many years secretary of the last named society and served for one term as its president. He was always actively interested in this association and it was very largely through his enthusiasm and untiring labors that the society was built up into a strong organization with a large and active membership. He was personally known to every member and was popular with all, and his death leaves a void that will be hard to fill.

Service Bureau.

Regular subscribers to the MEDICAL RECORD who desire information on any professional matter are invited to send their inquiries to the office of publication. Replies will be sent by mail as promptly as possible. Questions and answers of general interest may be published from time to time. When abstracts of articles from other journals are furnished the cost of typewriting will be charged.

Purchases will be made of articles of any description wanted by subscribers; a check sufficient to cover the cost should be sent with the order.

Subscribers visiting New York are welcome to use the office, 51 Fifth Avenue, as a temporary address for receiving and forwarding mail, telegrams, or small packages.

Correspondence.

THE QUESTIONABLE QUESTIONNAIRE.

To the Editor of the Medical Record:

Sir:—Your editorial on the questionableness of the questionnaire states the matter truthfully and effectively as it seems to me. The questionnaire method is not a very good way of reaching truth, at the best. It appeals to those who are opinionated rather than to the judicious.

Then it is very hard to say that any medical remedy is a necessity. Schools of Medicine have flourished without using opium or mercury or quinine in what we call medicinal doses. The doctors who say "yes" and those who say "no" to the question "is beer a necessity as a medicine?" must have very different conceptions of what is a necessity.

It is said that the purpose of medicine is "to cure sometimes, to relieve often, to solace always." Anything that enables the doctor to accomplish these things most effectively may I suppose be called a necessity. If Dr. A. uses such medicines as give better results and a larger practice than Dr. B, these medicines are his necessity, and he would answer "yes" to a questionnaire. On the other hand the very conscientious, meticulously ethical, and scientifically organized medical mind would probably say "no" to nearly every questionnaire that asked "is this specific medicine a necessity?" I should say that a questionnaire with the alternative "or important" would have made the interrogation a fairer one.

OUR LONDON LETTER.

(From Our Own Correspondent.)

London, December 27, 1921.

Sterility in Women.—At a meeting of the London Association of the Medical Women's Federation held on December 13 last, at the Elizabeth Garrett Anderson Hospital, the question of sterility was discussed. Papers on the subject were read by Drs. Christine Murrell and Elizabeth Bolton. Dr. Murrell traversed briefly the possible causes of sterility, laying especial stress on the importance of considering the condition of the husband as well as the wife. She directed attention to the fact that where active spermatozoa were present in the seminal fluid, sterility might be due to incomplete or too rapid coitus, to mechanical obstruction to the upward passage of spermatozoa, for instance, in cases of uterine displacement, cervical obstructions, or profuse discharge from or stenosis of the internal os. The uterus lining might be unsuitable for imbedding, or there might be disease of the tubes or of the ovaries. Moreover, putting mechanical causes on one side, and these could frequently be treated successfully by operative measures, there was still a good deal of work to be done in the study of the endocrine glands as they affected pregnancy. Dr. Murrell dealt at considerable length with the hormone theory of sterility, and the effects of administration of preparations of thyroid, posterior pituitary, thymus, and ovarian extracts on menstruation, ovulation, and pregnancy, pointing out the different endocrine preparations which might be expected on theoretical grounds to be of value, and the particular conditions in which she had found them useful. Dr. Bolton read a summary of 150 cases of sterility which had been treated by her. Of this number 122 were really treated, of whom 63 became pregnant. She found that these cases fell into four different groups, according to the gynecological findings, and she had found a gynecological abnormality in the entire 150 cases; 86 had marked anteflexion, the majority of these had an elongated cervix pointing forward, 20 had retroversion, 28 fibroids, 16 were tube cases. Of the 86 anteflexion cases 16 were untreated; of the remaining 70, 40 became pregnant; 52 had a dilatation and curetting, of these 27 became pregnant; 19 merely had a sound passed and 10 became pregnant; 2 had vaginal septa and became pregnant later; 1 had injection of semen twice, after 2 dilatations, but with no result. One had an exploratory operation, when the ovaries were found to be adherent and were freed, and a dilatation was also done, and this patient became pregnant. In all these cases the passage of the sound and dilatation were done, if possible at such a time as to allow intercourse before the next period. The time of pregnancy, in relation to the operation, varied greatly; in the majority of cases it occurred within a few months, in a few cases at once, and in a few others after two or three years, but Dr. Bolton had not heard of any after a longer period than three years. Several of the dilatation cases were operated on owing to dysmenorrhea as well as sterility, and many of these were much better from the point of view of the dysmenorrhea, though they did not become pregnant. Of the 20 retroversions 2 were untreated, 13 of the 18 became pregnant; 11 were replaced and a Hodge pessary inserted; 4 of these had a dilatation, 2 had a sound passed. Of the 11 cases treated with a Hodge, 7 became pregnant. Two retroversions with adherent tubes had an exploratory laparotomy and both later became pregnant. Five Gilliam operations were done for sterility and 4 of these patients became pregnant. All these had the right tube only involved, complicated by the appendix. Of the 25 fibroid cases, 4 were untreated; of the remaining 21, 7 became pregnant, 2 of these had a large polyp removed by the vaginal route, the other five had several fibroids removed by abdominal myomectomy. Dr. Bolton usually advised myomectomy patients to avoid pregnancy for six months after the operation. She had had one patient from whom she removed two large fibroids by myomectomy, who was found at the time to be about two months pregnant. The woman had had no previous pregnancy, had been married fourteen years, and was 42. She went to term satisfactorily. Dr. Bolton noted that all of this small number of cases had a gynecological condition that might account for the sterility, and that over 51 per cent. of all the women treated became pregnant.

Puerperal Infection.—At a meeting of the West London Medico-Chirurgical Society on December 2, a discussion on the treatment of puerperal infection took place. The discussion

was opened by Dr. Frederick J. McCann, who began by comparing the nature of puerperal infection with that of ordinary septic wounds. The normal sequence of events in a healthy puerperium was attained chiefly by the increased vascular and lymphatic supply of the involuting uterus. He emphasized the importance of wounds of the cervix, vagina, and vulva as sources of infection and criticised the orthodox teaching that infection usually originated within the uterus. He then alluded to the modes of spread and the general course of the infection and discussed the importance of prophylactic measures. He pointed out the defectiveness in the hospital system in that it provided such scanty accommodation for puerperal cases. The teaching of obstetrics should also be improved. Medical officers of health should be empowered to admit to hospital women whose domestic surroundings were unsuitable for a confinement. The application of forceps and the introduction of the hand into the uterus should be regarded as a major operation. Rectal examination should be avoided, its disadvantages were obvious. Vaginal and perineal wounds and deep cervical tears should be carefully cleansed and sutured. As for the treatment of infected cases, in the first place extragenital sources of infection must be excluded. Exploration of the uterus was only permissible in the severer types of cases or after any likely source of infection in the lower genital tract had been excluded. The curette should be used as a probe only, or for gently removing any loose fragments, and never as a scraper. Puerperal peritonitis and localized abscesses must be dealt with on ordinary surgical lines. Subcutaneous injections of saline solution, free purgation, and the judicious use of quinine were all valuable. Serums and vaccines were on the whole disappointing.

Dr. Remmington Hobbs believed strongly in uterine drainage, as in his opinion the rise of temperature was due to mechanical blocking of the uterine outlet by malpositions of the uterus, edema of the cervix, and overloading of the rectum. For the purpose of clearing the way he used a small rubber catheter. After cleansing the genital passages the catheter was introduced into the uterus by means of a special forceps made to his design, 10 c.c. of a glycerin and iodine mixture, in the proportions of 7 to 1, was then injected into the uterus. It might be necessary to repeat this injection on several consecutive days, according to the course of the temperature charts which bore out the efficacy of this line of treatment. Dr. Knyvett Gordon stated that an experience of 250 cases had led him to believe that the best line of treatment was curettage, saline infusions, and the use of antisera in large doses combined with saline. Laparotomy and even hysterectomy were indicated in the severer cases. Dr. Bernard Spilsbury referred to the severe type of case seen by him, in some of which death occurred as early as 24 hours after infection. There was in these cases little macroscopic evidence to account for the infection. Dr. J. Burnford laid stress on the importance of bacilluria as a cause of fever during the puerperium. Bacteriological examination of the urine should be a routine procedure in puerperal cases associated with pyrexia.

King Edward's Hospital Fund for London.—A meeting of the General Council of King Edward's Hospital Fund for London, held with the object of awarding grants, took place on Dec. 14 last. Lord Revelstoke, honorary treasurer, said that the amount received for general purposes to Dec. 3, 1921, was £221,326. This exceeded the total indicated in the estimate laid before the Council in November, the increase being due to the generous action of King George's Fund for Sailors in again providing the amount of the grant of £5,000 to the Seamen's Hospital. The legacies received during the past eleven months amounted to £74,000, as against £18,000 in 1920, and the Council had decided to distribute a portion of these additional receipts, and to retain a portion in reserve. Lord Revelstoke then read the following letter from Lady Mount Stephen: "I have been allowed to tell you by the executors that my husband has left the residue of his fortune to King Edward's Hospital Fund. It is, I believe, practically nearly the whole of his fortune, for the legacies, etc., in proportion do not amount to anything of importance." Viscount Finlay moved a resolution recording the deep regret of the General Council of the Fund at the death of Lord Mount Stephen, to whose benefactions the Fund and the sick poor of London owed so much. His gifts to the capital of the Fund during his lifetime amounted to some £500,000. The late Lord Strathcona and the late Lord Mount Stephen were born in Scotland, within a few miles of each other, of poor parents. They emigrated to Canada when young and both made immense fortunes. Both, too, were instrumental in rendering the making of the Canadian Pacific Railway possible, and they both gave lavishly to charity and especially to hospitals. The magnificent Victoria Hospital in Montreal is a standing tribute to their munificence. Lord Mount Stephen's posthumous gift to the London Hospitals is exceedingly timely and should greatly aid in tiding them over their present difficulties.

Experimental Rickets.—Recently there has been published by the Medical Research Council a report on experimental rickets by Dr. Edward Mellanby. There is, at the present time, a good deal of confusion or, at any rate, there are wide differences of opinion with regard to the etiology of rickets. Some hold, and hold strongly, that the condition is mainly due to want of fresh air and exercise, and that diet plays but a small part in its causation. Others, of course, and these are in the majority, retain the old view that rickets is brought about by an ill-balanced diet, and especially by a diet lacking in the essential vitamine elements. Dr. Mellanby in a former report laid much stress on the absence or deficiency of the fat-soluble A vitamine, and attributed to this cause the initiation and development of the condition. In the report just issued these opinions are considerably modified and not so much attention is directed to the importance of the fat-soluble vitamine. Mellanby's conclusions are as follows: "To combine the facts into a simple general hypothesis, at this stage of the work at least, seems impossible except to state that some elements of the diet assist in the calcification of bone, antirachitic vitamine and others inhibit it. The greater the growth the more necessary it is to have in the diet and absorbed

from the alimentary canal, substances which aid in calcifying bone, *e.g.* calcium, phosphorus, and antirachitic vitamine. If these latter substances are relatively deficient or defective in their action rickets will result. In addition to the dietetic elements there is the effect of exercise to be considered. This aids the process of calcification. But if a child is correctly fed, the question of exercise appears to Mellanby to be negligible, partly because exercise is not so necessary when calcification processes are strongly stimulated by the dietetic elements and partly because an adequately fed child will get exercise in the form of small movements under any conditions. If children are improperly fed, from the point of view of this research, they will almost certainly react, as shown in the case of puppies, by not taking exercise.

OUR LETTER FROM SWITZERLAND.

(From Our Own Correspondent.)

GENEVA, December 5, 1921.

Epidemic Hiccough.—I am able to give some data relating to that peculiar morbid process, epidemic singultus, as it has appeared in Switzerland. The first cases observed developed in the winter of 1919-20, and Dr. Gautier describes them as occurring in subjects otherwise perfectly well, except that in some the condition was accompanied by a febrile state, but of no severity whatsoever. The singultus developed suddenly, lasting for hours without intermission and then after a phase of calm a paroxysm of coughing or some effort on the patient's part caused the spasms to return. The affection sometimes lasted for as much as four days and then disappeared rather suddenly. Gautier regards these abnormal forms of singultus as special forms of encephalitis lethargica resulting in a disturbance of the phrenic nerve, which might be either an attenuated, isolated manifestation of the disease or a prodromic sympton of encephalitis. It was especially toward the end of 1920 that this curious affection began to multiply and attracted the attention of the profession, and it was only then that the Federal Health Board issued instruction to report all cases, so that the data to hand included only 46 cases reported during January, February, and March, 1920, and 17 reported from Bâle from the end of October, 1920, to January 31, 1921. One case was reported in Geneva in May, 1921, so that the total amounts to 64 known cases.

The disease attacked adults. In some instances the singultus persisted for a week, in others it disappeared in a few hours. It subsided quite as quickly as it developed. The hiccough was sometimes so severe that the patient's bed was actually shaken. In one case the spasm disappeared and then shooting pain in the knees and legs ensued, true algias recalling those of encephalitis lethargica. In another case the singultus coincided with an erythema extending all over the face, while in still another there was at the same time an attack of acute gastritis with vomiting and complete intolerance for food.

Some of the cases remained apyretic, while in others the temperature reached 101° F. The sensorium was not usually involved, though a few patients presented a little mental cloudiness. The cases were in general scattered about and only occasionally were there little foci in families or in certain localities. Their relation to influenza or encephalitis lethargica could rarely be determined. Thus, in one instance the son of the family contracted epidemic singultus and a few days later the father came down with encephalitis lethargica. In another case the singultus followed upon an influenzal bronchitis and then had been one case of encephalitis in the neighborhood. Finally, in another case, the singultus developed after an attack of cerebrospinal meningitis. These scattered and fragmentary indications are quite insufficient to elucidate the etiology of epidemic singultus or to back the opinion which is tending to become more generally accepted, namely, that the hiccough is nothing else than a monosymptomatic form of the myloclonic syndrome of encephalitis lethargica. Hence what data have been given are merely documents that may serve for the general study of this process and are by no means intended to settle the subject.

Dr. Ludendorff.—The mentality of the German is weird. The Faculty of Medicine of the University of Koenigsberg, Prussia, has thought fit to confer the degree of M.D. honoris causa on General Eric Ludendorff. Just why this particular degree should have been chosen for a military man remains obscure, but it is possible that the Faculty were indebted to him for a large amount of clinical material and desired to evince its appreciation by this abnormal demonstration of esteem.

Notifiable Diseases.—The Swiss Federal Council has decreed that the following epidemic diseases must be reported: Variola, cholera, typhus fever, plague, epidemic dysentery, scarlet fever, diphtheria, typhoid fever, paratyphoid fever, epidemic cerebrospinal meningitis, acute anterior poliomyelitis, encephalitis lethargica, influenza, malaria, leprosy, and trachoma. A merely suspicious case of any one of these affections must be reported. In the case of smallpox, cholera, typhus fever, plague, and epidemic dysentery, the notification must be made individually, and sent immediately by the attending physician to the nearest sanitary authority. When the diagnosis of any of the above-named diseases has only been made post-mortem the cause of death must be given. The notification must mention the name, sex, and age of the patient, his social position or profession, his abode or place of birth, the date of the onset of the disease, the provisional measures taken, and, if possible, the source of infection, as well as all other useful indications. In the case where a physician has not been summoned the head of the family or any other adult person of the neighborhood, or if the patient resides in an hotel, boarding house, or school, the director of the establishment is under obligation (before the law) to notify the proper authority. This authority shall see to it that a physician visits the patient within the shortest time possible in order to make a positive diagnosis.

For scarlet fever, diphtheria, typhoid fever, paratyphoid fever, epidemic cerebrospinal meningitis, acute anteria poliomyelitis encephalitis lethargica, influenza, malaria, leprosy, and tra-

choma, notification should be made according to the rules of each canton, the authorities of which shall send each week their reports to the Federal Service or Public Hygiene. This report shall also mention transmissible diseases which are not included among the above-mentioned affections, the notification of which is compulsory in the given canton—varicella, measles, erysipelas, pertussis, mumps, puerperal fever, etc.

3. Two Different Views of Stammering. Ernest Tompkins.
4. The Basal Metabolism in Myelogenous Leucemia and Its Relation to the Blood Findings. Arthur H. Gunderson.

2. What May Be Expected from Sanatorium Treatment?—Vincent Y. Bowditch reviews briefly the history of the growth of sanatoria during the past fifty or sixty years, both abroad and in the United States, and makes it very plain that no claim was ever made by those who best understood tuberculosis that by the establishment of sanatoria the panacea had been found for exterminating the disease. The result of his experience at Sharon Sanatorium has firmly convinced him that every dollar spent for the support of *properly regulated* sanatoria has been more than repaid by what they do to promote the health and welfare of our communities, not only in restoring people to health, but as a large factor in the field of preventive medicine. The open-air school combined with sanatorium life has a wonderful effect on young children, of which the writer feels he can speak with more assurance than formerly. For some reason there has not been the response to this movement which it merits. Physicians are urged in their practice to keep in mind the value of the "preventorium" for children. The sanatorium is one of the vital factors in the whole field of our efforts to eradicate tuberculosis; an adjunct to every other possible means that we can furnish for its cure and prevention. This opinion is now shared by everyone who has had any experience in this special direction.

3. Two Different Views of Stammering.—Ernest Tompkins discusses the various theories of stammering and more particularly that of Bluemel, that stammering is caused by transient auditory amnesia in the auditory speech centers brought on by cerebral congestion. He argues that the Bluemel theory is admittedly a failure for approximately half the cases, and evidently a failure for all the rest. This applies to any theory which imputes a "failure" or "lack" to the stammerer. The visual-asthenia theory, the enlarged thymus theory, the neurosis theory, the psychosis theory, the Freudian theory, any and all theories of the "lack" or "deficiency" class, are as perfect failures as the Bluemel theory. The stammerer's difficulty is not lack of anything—of healthy brain cells, of coordinating ability, of intelligence—it is a superfluity, namely, the mistaken idea that his speech is defective. The speech-interference theory is in harmony with the facts and explains all cases of stammering. Stammering is not a disease, it is a habit. When the stammerer forgets his difficulty his speech flows unimpeded. This habit is kept fastened on the race by the suppression of its true nature and by the dissemination of fallacious disease theories.

4. Basal Metabolism in Myelogenous Leucemia and Its Relation to the Blood Findings.—Arthur H. Gunderson has made sixty-two observations of the basal metabolism on nineteen cases of myelogenous leucemia which indicate that the basal metabolism in myelogenous leucemia bears a relation particularly to the number of immature white cells in the blood stream, regardless of the total leucocytosis. The highest values for basal metabolism are usually found in cases with very high white counts and many myelocytes, or in cases showing high percentages of myeloblasts. Both of these findings probably signify activity of the leucopoietic tissue and that basal metabolism determinations may be considered as indices of this activity.

1. Type I Pneumonia and Its Serum Treatment.—William S. Thomas bases this paper on a series of sixty cases of Type I pneumonia treated in St. Luke's Hospital, New York (fifty of them with and ten without serum) and on 550 cases reported in the literature exclusive of the Rockefeller Institute series. The material collected indicates that Type I pneumonia, however treated, varies in its mortality rate with the time and place of its occurrence, and suggests that it may perhaps be not so frequently fatal as is generally believed to be the case. Administration of the specific serum in Type I pneumonia appeared to shorten the disease in four of the fifty treated cases of this series. In eight of them the use of the serum, though followed by improvement in the symptoms, appeared to have only a transitory effect. Among the remaining thirty-eight patients the duration and outcome of the disease do not appear to have been demonstrably affected by the serum. The average duration of the fever among the serum-treated cases was nine and one-half days; among those not treated specifically (ten cases) it was eight and two-tenths days. Two deaths from anaphylaxis due to antipneumococcic serum are reported in the literature. Ten patients of this series suffered from anaphylaxis and were relieved by epinephrin. Of these ten shocked patients, six had previously shown no reaction to dermal tests for sensitiveness to horse serum. Skin tests with the protein of horse epidermis, as well as with that of horse serum, should precede the intravenous injection of the latter. Serum sickness followed the therapeutic use of Type I serum in thirty-six of fifty cases. In fifteen the symptoms were severe. Epinephrin allays the discomfort of the eruption temporarily.

2. The Mode of Production of the So-Called Vesicular Murmur of Respiration.—George E. Bushnell summarizes his investigation on this subject as follows: (1) The selective action of resonators plays an important part in determining the characteristics of sounds within the respiratory apparatus. (2) The specific character of vesicular breathing is due to the resonator, the thoracic cavity, the sound at the place of origin being merely a noise, some element of which is capable of exciting the syympathetic resonance of the thorax. Hence sounds produced without the aid of the larynx may imitate vesicular inspiration. (3) Reciprocating breathing shows that sounds may be produced by currents of air within the lung. The pitch of these sounds is the same as that of vesicular breathing, the audible vibrations of both sounds being those which the thorax as a resonator reinforces and which the lung substance, a poor conductor of sound, is able to transmit. (4) Experiment in which the sounds of respiration over the chest disappear when the glottis is opened wide seem to prove that the sound of inspiration as well as that of expiration originates in the larynx.

3. The Deleterious Effect of Sodium Citrate Employed in Blood Transfusion.—Lester J. Unger has long held that from the biological point of view the delicate blood tissue has been changed, because of the chemical

and physical alterations brought about by the addition of sodium citrate and by its sojourn outside the vessels. Whole unmodified blood, however, flows almost from vessel to vessel and is given to the patient in an unchanged condition. For diseases, therefore, in which the transfusion of blood is indicated for itself, as in the various anemias, blood diseases and infections, there can be no question as to the superiority of whole unmodified blood. In cases of hemorrhage, on the other hand, when the purpose is not so much to replace pathological with normal blood, but rather to replenish the impoverished circulation or to bring about cessation of hemorrhage, citrated blood may serve as a substitute. Because of clinical evidence leading to these views, laboratory experiments were undertaken to investigate the differences between modified and citrated blood. From these the conclusion is reached that sodium citrate, even in the low percentage employed in a citrate transfusion, affects the red blood cells, rendering them more fragile. The value of such blood to a patient suffering from a hemolytic disease, such as pernicious anemia, is lessened to that extent. Sodium citrate diminishes the available complement in two ways: by its direct action on complement itself and by introducing into the plasma an anticomplementary substance which inactivates complement. This substance is derived directly from the bodies of red blood cells. Sodium citrate also reduces almost to nil the function of opsonins, and practically destroys the phagocytic power of white blood cells. Furthermore, the phagocytic index of the blood of various donors differs. Since complement and phagocytic powers are of prime importance in the protective action against pathogenic organisms, unmodified blood from a donor with high phagocytic index should be employed when attempting to combat local or general infection by means of transfusion. In selecting a donor attention should be paid to the finer qualitative differences in the blood.

4. Ratio Between Deaths from Traumatic Fracture of Cranial Bones and from Alcohol.—Edward H. Hatton has compared the death rate in Chicago due to the poisonous action of alcohol alone (including delirium tremens) with the death rate due to skull fracture during the period from February, 1914, to and including August, 1921. Aside from very notable variations, the parallelism of the skull fracture and alcohol curves is unquestionable. Both curves gradually ascend during the years 1914 to 1917. At the end of 1917 both drop abruptly to a new low level, and, except for three high peaks in the skull fracture curve, maintain their parallel course up to the present low level. The drop in 1917 coincides with the entrance of the United States into the World War and the curtailment in the manufacture of alcoholic beverages. The continued drop in the curve corresponds clearly with the increase of activities directed at curtailment of the consumption of alcoholic beverages. The three peaks in the curve of skull fracture deaths seem to be connected with such events as icy and slippery sidewalks, stairways and porches; and in warm weather with accidents occasioned by falling from open windows, over porch railings and down stairs. It does not seem possible to associate the parallelism in these two curves with economic or social factors, or with such movements as "safety first" crusades.

5. Spontaneous Closure of Intestinal Perforation: Report of a Case of Double Infection with Typhoid and Paratyphoid B.—B. M. Randolph and Oscar B. Hunter find this case of interest for several reasons. It seems likely that the patient had been suffering from active typhoid for two or more weeks before coming under observation. The Widal reaction was strongly positive at all examinations. The blood cultures were negative throughout. It is not unlikely that the period during which bacilli could be found in the blood stream had passed before the patient sought medical advice. However, there is a possibility that previous antityphoid inoculation may have been responsible for the negative blood cultures, as one of the writers has observed typhoid in an immunized person, in whose case the blood cultures were negative throughout, although at autopsy the bacilli were recovered from the spleen. The case is also noteworthy because of the simultaneous infection with typhoid and paratyphoid B, which is an uncommon finding, though not unprecedented. The most important feature of the case was the demonstration at necropsy of a spontaneous closure of a perforating typhoid ulcer. Three perforations were found: One that was closed at operation; another, patent, which from the absence of any appearance of local reaction, evidently occurred subsequent to the operation, which was performed a few hours before death; a third which was firmly closed by abundant adhesions, and which, from the evidences of repair shown about its margins, evidently occurred some time before death. From the clinical course of the case it seems obvious that this perforation took place at a time when such an event was suspected. It is probable that spontaneous closure of typhoid perforation occurs more often than we realize.

8. Gastric Analysis. iv. The Gastric Equilibrium Zone.—Chester C. Fowler, William H. Spence, Martin E. Rehfuss, and Philip B. Hawk, in the course of their gastric studies, have introduced into the human stomach a considerable number of fluid substances of widely divergent character in order to secure data in regard to the response secured. Among the substances were water, hydrochloric acid, sodium bicarbonate, sodium chloride, tea, vinegar, etc. They find that the mechanism by which the stomach brings all fluids to an optimum acid level before permitting their evacuation into the intestine is a most remarkable one. It is closely associated with Boldyreff's mechanism. The area in which the gastric acidity values fall after the ingestion of fluids of widely divergent character the writers have called the gastric equilibrium zone. This zone varies for different individuals, being relatively high for high acid stomachs and relatively low for low acid stomachs. This mechanism is practically or wholly lost in disease.

5. Aortic Incompetence: A Clinical Study. George J. Langley.
6. On the Non-Lactose Fermenting Bacilli in the Stools of Healthy and Unhealthy Uganda Natives. H. Lyndhurst Duke.

1. An Address on Some Heart Problems.—Ernest H. Starling discusses the phenomena of uncompensated heart disease and shows that the essential factor is diminished output. He says it is hardly conceivable, however, that the heart in situ, unable to respond to the demands made upon it, does not itself invoke the interaction of the central nervous system, which may be used either to increase the response of the heart muscle, as certainly occurs in the healthy individual, or possibly to save the muscle at the expense of other organs of the body, subject only to the demands of the brain itself, when the heart is in danger of failing because of excessive fatigue. It is possible, too, that other factors, such as retarded rate of relaxation, may serve to diminish the rate of inflow into the tired heart. After describing the way in which rest, oxygen and diminution of plethora aid in restoring the physiological function of the heart, attention is called to the importance of the circulation through the coronary vessels. In his earlier experiments on the isolated heart-lung, Starling says he used to put the arterial pressure low in order, as he thought, to give the heart as little work as possible to do. Many hearts after the artificial circulation had been established continued to fail and finally went into delirium or ceased to beat. One day he put the pressure to 150 mm. of mercury, thinking that he should kill the heart outright. Instead the heart first dilated and then beat more forcible, but as it reacted to the pressure it steadily improved, and both its systolic and diastolic volumes diminished. He thus found that as soon as an adequate supply of blood through the coronary arteries was furnished the heart steadily improved and was able to contract through an abnormally high resistance without undue dilatation, with improvement in the physical condition, and increased tone of this organ. He is inclined to ascribe the beneficial effects of graduated exercises in heart

disease very largely to the improvement of the coronary circulation brought about by the temporary rise of arterial pressure accompanying the exercises. The most important factor in determining the amount of flow through the coronary arteries, and therefore the oxygen supply to the heart muscle, is the arterial pressure so that as the resistance to the heart beat increases there is a corresponding increase in the flow of blood through the heart muscle. Under extreme conditions of work the flow through the heart muscle may be greater than has been found in any other organ of the body and may amount to 5 c.c. of blood per minute for every gram of heart muscle. The supply of blood and oxygen is aided by two more circumstances: (1) As soon as increased strain is thrown on the heart, or this organ commences to fail, there is an augmented flow through the coronaries out of all proportion to the blood pressure in the aorta. This is not due to the accumulation of carbonic acid in the blood, and must be determined by the formation of metabolites, of which lactic acid may be one, in the laboring muscle fibers. Moreover, the heart has an astounding power of utilization of oxygen in the blood. When an isolated heart is fed with blood from an asphyxiated animal, the heart removes the last traces of oxygen from the blood, so that the blood from the coronary sinus does not contain one-half per cent. of oxygen. The enormous range of adjustment in the coronary circulation characteristic of the healthy heart enables one to form some idea of the evil results which must follow impairment of the power of adjustment.

2. **On the Function of the Lymphocyte and of Lymphoid Tissue in Nutrition, with Special Reference to the Vitamine Problem.**—W. Cramer, A. H. Drew and J. C. Mottram find that absence of water-soluble B-vitamine from the diet leads in rats and mice to an atrophy of the lymphoid tissue throughout the body and to a lymphopenia in the circulating blood. The polymorphonuclear leucocytes are not affected. Absence of fat-soluble A-vitamine does not lead to an atrophy of the lymphoid tissue and there is no lymphopenia. Absence of water-soluble B-vitamine leads to characteristic nutritional disturbances such as loss of weight, emaciation, subnormal temperature which may be designated by the term "marasmus." No such marasmus results from withholding the fat-soluble A-vitamine. The lymphopenia established by withholding the water-soluble B-vitamine is rapidly abolished by the administration of the water-soluble B-vitamine, and with it the concomitant marasmus. A permanent lymphopenia, associated with atrophy of the lymphoid tissue and nutritional disturbances similar to those produced by withholding water-soluble B-vitamine can also be induced by exposure of rats to sufficient doses of *x*-ray or radium. Since the functional disturbances in lymphoid tissue produced by two such widely different agencies lead to the same nutritional disturbances it is concluded that the lymphocytes play a part of fundamental importance in the nutrition of the body. Other evidence points to the conclusion that they are concerned in the absorption and assimilation of food from the intestine. The conception that vitamines—and B-vitamines in particular—are necessary for the life of every individual cell is criticised. This vitamine is necessary for the maintenance of life of a highly differentiated animal, not because its presence is necessary for the life of all the cells of such an animal, but because its presence is necessary for the normal functioning of the lymphoid tissue. In other words, the term "deficiency diseases" is, like the term "vitamine," a misnomer. These diseases have their origin, like other diseases, in specific lesions, which may be produced by different agencies of which a deficiency in vitamines is only one.

4. **The Effect of B-Vitamine on the Appetite.**—Samson Wright describes his experiments on rats and summarizes those of others reported in the literature, from which it appears that there is a considerable accumulation of evidence that the appetite is adversely affected by the absence of B-vitamine from the diet of animals. His experiments led him to believe that vitamine B acts by facilitating the carrying out of the functions of the intestinal canal. The main effects produced by the absence of the vitamine, namely, diminished food consumption, loss of weight, and ultimate death, are due to intestinal stasis and the absorption of toxic bodies which results therefrom.

1. Mitchell Banks Memorial Lecture on the Surgeon as Pathologist. C. J. Bond.
2. Treatment by Inflation of Oxygen. Ernest Rost.
3. Persistent Cloaca with Imperforate Anus as a Cause of Fetal Ascites. John N. Cruickshank.
4. Curettage and the Treatment of Uterine Hemorrhage. Beckwith Whitehouse.
5. Position of the Practitioner Called to a Case of Procured Abortion. John Campbell.

1. Mitchell Banks Memorial Lecture on the Surgeon as Pathologist.—C. J. Bond calls attention to some facts of physiological significance which have come to his notice in the course of his work during the war, which he summarizes as follows: (1) A capacity to elaborate a substance or substances closely allied to, if not identical with, glycogen is possessed by leucocytes, myelocytes, and certain epithelial cells. (2) In the case of white blood cells this capacity is in the main limited to the polymorph leucocytes when they emigrate or escape from the blood stream. (3) In the emigrated leucocyte this glycogenic substance takes the form of a colloid liquid which is rapidly exuded from the cell, and gives a delicate mauve color with iodine. (4) In the myeloid cells of the red marrow and in some myeloma cells this substance is also present and is somewhat evanescent. (5) In certain epithelial cells of the mucous membranes which line the orifices of the digestive, respiratory, and genitourinary canals, this iodophil substance is present in a more granular and less soluble form. It is closely incorporated with the cell cytoplasm, and stains a red or red-brown color with iodine. (6) The same or an allied substance is also constantly found in certain cancer cells of epithelial origin. (7) In the primary growth it is present in the cells which form the cell nests. In common with the irregular growth of the epithelial cells in the cancer area the disposition of the iodophil epithelial cells also undergoes a change. These are reduced in number, and are collected in irregular groups rather than in stratified layers. (8) This iodophil substance is also present in the epithelial cancer cells found in the lymph glands and in other secondary deposits. (9) The presence of this capacity for elaborating iodophil substances by cancer cells in secondary deposits is an indication of the retention of some degree of original function by these cells in their abnormal situation, and is associated with important problems of cell heredity. (10) Myeloma cells have a genetic relation with red marrow cells on the one hand and polymorph leucocytes on the other. All these cells elaborate an iodophilic substance in a characteristically staining and soluble form. (11) The high glycogen content in mammary tumors of certain strains in mice seems to be connected with the strain—that is, the hereditary origin—rather than with a high degree of malignancy in the cells of such cancers. (12) The proportion of iodophil cells in the epithelial covering of the endometrium varies greatly, both in different individuals and in different areas of the same uterus. This may probably be connected with the periodical changes in cell metabolism which occur in the organ. (13) There are some facts which suggest an association between activity in glycogen formation and resistance to infection. In leucocytes the iodophil substance seems to be exuded into the surrounding medium on the disintegration of the cell. In epithelial cells the iodophil substance is present in a less soluble form, and remains in closer association with the cytoplasm of the cell. The fact that the distribution of the iodophil cells varies both in the mucous membranes of different individuals and in different areas of the same mucous membrane may be associated with a varying power to resist invasion by pathogenic organisms.

2. Treatment by Inflation with Oxygen of Tuberculous Affections.—Ernest Rost published in the *Indian Medical Gazette* of September 9, 1920, a preliminary note of the treatment of tuberculous affections of the enclosed cavities, abscesses, and caries, by inflation with oxygen. Since then the treatment has been extended in its application, with very remarkable results, to psoas abscess, tuberculous peritonitis, tuberculous

joints, infection of a compound fracture with *B. aerogenes capsulatus*, multiple pyemic abscesses, chronic synovitis of the knee-joint and fibrous ankylosis of the knee-joint. After aspirating the fluid from the cavity to be inflated the aspiration portion of the apparatus is turned off and connection made with the inflation portion of the apparatus. The oxygen is passed through a wash-bottle and a cotton-wool tube and is warmed and rendered sterile. After the aspiration is made a purse-string suture is applied around the entrance of the needle and pulled tight as the needle is withdrawn. It would appear that the gas has the property of separating surfaces which are adherent by plastic lymph in chronically inflamed conditions of the peritoneum. The distension of a joint by gas prevents the apposition of inflamed surfaces, and the pouring out of serous fluid by internal pressure to the secreting surfaces. It seems that the oxygen exerts some inhibitory effect on the pathogenic process.

4. **Curettage and the Treatment of Uterine Hemorrhage.**—Beckwith Whitehouse groups cases of pathological uterine hemorrhage under one of the following headings: (1) Menorrhagia, a term limited to excessive hemorrhage relating simply to the quantity of blood lost at a menstrual period. (2) Menostaxis, denoting excessive menstruation as regards duration of the flow, the discharge consisting chiefly of the secretion of the uterine glands. (3) Epimenorrhea, signifying too frequent menstruation, in other words, an alteration of rhythm. (4) Metrostaxis, denoting uterine hemorrhage apart from and having no relation with menstrual bleeding. It includes not only all hemorrhages before puberty and after the menopause, but also all irregular bleeding during a woman's active sexual life. This classification the writer has found very useful in practice, as it divides one's cases into well-defined groups, and affords a basis for investigation and treatment along rational pathological lines. Whitehouse repeats his protest against indiscriminate curetting for all cases of obscure uterine hemorrhage. The operation may do good, but the chances are equally against it if the cause of bleeding is not directly dependent upon pregnancy. As a diagnostic procedure, however, curettage is of paramount importance, especially when the microscopical appearances of the endometrium are considered in relation to the history of the case and the character of the uterine discharge. To curette a uterus and throw away the curettings is comparable to treating hemoptysis without examining the sputum. Hemorrhage from the uterus is a symptom of such diverse conditions involving the whole realm of medicine that no one remedy such as curettage can ever be expected to prove effective in all cases. Radium is no doubt a valuable agent for controlling uterine hemorrhage due to ovarian and endometrial incoordination. It is also a useful remedy in those cases due to hypertrophy or atrophy of the endometrium. In checking hemorrhage at puberty and the menopause radium must exert its peripheral action on the ovaries, as the endometrium is inactive from underdevelopment or atrophy respectively. When uterine hemorrhage is the result of incoordination of various hormones, curettage will be but palliative, or will fail completely, unless combined with other therapeutic measures designed to combat the primary cause.

Vincent's Angina and Intestinal Spirillosis.—Bouchet and Leroux relate a case which sums up as follows: a man, aged 25, first suffered from pyorrhea alveolaris, upon which there developed an ordinary case of Vincent's angina. This was in April, and in the following May there followed an attack of acute enteritis. One year later there was a second attack of angina, after which the patient was treated with salvarsan; since which he has remained free from all symptoms. The authors cannot demonstrate that the intestinal trouble was due to the exciters of Vincent's disease, but this sequence is highly probable. We know now to a certainty that this affection is a pure spirillosis, the fusiform bacillus playing no rôle in causation. The spirilla as a class have been suspected before of the ability to cause enteritis. There are members which dwell in the intestine as harmless saprophytes which are probably capable of becoming pathogenic at times. While the authors use the term spirillum in a general sense they clearly refer to Vincent's spirillum, while at the same time the existence of other forms is sometimes implied. A description of the spirilla of angina and those found in the stools of subjects with enteric diseases shows both conformity and divergence. The germ found in the mouth appears to agree with the so-called buccal and dental spirochete, while there were two distinct forms in the intestine, one of which conformed to the buccal spirochete. One faction of bacteriologists state that the spirilla of the mouth are multiform, indicating either different species or varieties, and the same may be said of the intestinal forms. Others definitely separate the dental from Vincent's spirochete. Despite the confusion in detail there is no doubt that banal spirochetes are able to set up a considerable variety of lesions under certain circumstances.

Le Progrès Médical.

November 26, 1921, xlix, 43.

Atony of the Stomach.—Ramond refers to recent advances in diagnosis, chiefly radiographic, which enable us to differentiate atony of the stomach from conditions which resemble it. The body of the stomach is separated from the fundus by a sort of hour glass division and is elongated, often to a notable degree, the fundus lying low near the level of the pubes. The fundus undergoes no peristaltic movements and the bismuth pulp is found within it. These stomachs have a slightly increased capacity, but are not dilated; they bear a superficial resemblance to ptotic stomachs and the hour glass shape suggests gastrospasm. In the diagnosis of atony we must exclude all stenosis of the pylorus. The bismuth, after reaching the fundus, lies there for six hours or more, and this fact furnishes a presumption of atony. Clinically these subjects complain of anorexia with evidence of slow and incomplete digestion. Nausea is common, while pyrosis, cramps, and vomiting are exceptional. These patients are all air swallowers, and the atonic stomach readily distends. The chemism is not constant but varies with different conditions. There may be high acidity. In the management of this affection the meals should be small and digestible. In some cases two meals daily at 7 a.m. and 7 p.m. work well, but this necessitates large meals, and the author prefers the latter small and more frequently repeated. One eats very slowly, masticating well, and invariably lies down for half an hour after eating.

Schweizerische medizinische Wochenschrift.

November 17, 1921, li, 46.

Infection of a Wound with Vaccine Virus.—Schneiter reports the following case. On June 15 last an unvaccinated girl, aged 10 years, came under observation for an abraded wound on the left arm. Instead of healing, the lesion, after several days, became worse and the arm swollen. Ten days after the injury there was a large crusted sore the size of a silver dollar *in situ*. The margin presented a series of bullae suggesting vaccine pustules. The swelling of the arm was also of the type sometimes seen after vaccination. The general condition and mental state were but little affected, and this, too, is what is seen in the recently vaccinated. The diagnosis of abnormally situated vaccination lesion was made in the absence of an anamnesis. The latter, however, was readily obtained as patient's seatmate in school had been recently vaccinated, as had a number of other classmates. The precise mechanism of transmission was not learned. The lesion closed at the period corresponding to healing of a vaccination wound. The patient was at once inoculated twice with cowpox lymph and the result was negative. The case is by no means the first of the kind to go upon record, and the author cites a number of others of the same type, all of them during the present century. These shade into similar cases of autoinoculation. In one case of accidental heteroinoculation the lesions were severe, suggesting variola, and death occurred with symptoms of meningitis.

Book Reviews.

THE ELEMENTS OF PRACTICAL PSYCHO-ANALYSIS. By PAUL BOUSFIELD, M.R.C.S. (Eng.), L.R.C.P. (Lond). Physician to the London Neurological Clinic (Ministry of Pensions), Late Demonstrator of Morbid Anatomy, St George's Hospital, Late M. O. American Women's Hospital for Officers, etc., etc. Price $5. London: Kegan Paul, Trench, Trubner & Co., Ltd.; New York: E. P. Dutton & Co., 1920.

THIS book of Dr. Bousfield's goes a long step toward a saner presentation of the basic principles of this subject. There has been no attempt made to do any more than give the simple fundamentals of psychoanalysis. Whether the reader believes in this thing or not, he will find pleasure in the reading of this work. There is a simplicity of style that immediately catches the interest and holds it, causing the reader to wish that the author had not made his work so short—a rare thing these days, when every psychoanalyst seems to be in a frenzy to write as complexly as he can everything he thinks he knows. To those who are interested in psychoanalytic work but who are still in a state of confusion as to it, Dr. Bousfield's book is cordially recommended.

PHYSICAL DIAGNOSIS. By W. D. ROSE, M.D., Lecturer on Physical Diagnosis, and Associate Professor of Medicine in the University of Arkansas; Demonstrator of Clinical Medicine and Chief of the Medical Section of the Isaac Folsom Clinic; Visiting Physician Logan H. Roots Memorial (City) Hospital, Little Rock, Arkansas. Second edition. Three Hundred Nine Illustrations. Price $8.50. St. Louis: C. V. Mosby Co., 1921.

THIS is very thorough work on Physical Diagnosis. The author rightly emphasizes the value of a knowledge of anatomy as the basis for the study of diagnosis. He also draws attention to the various physical principles which underlie the different physical signs. In this way the study of diagnosis is made to depend upon the student's reasoning powers rather than upon his memory. The illustrations are particularly good; they are numerous and show clearly the points which the author desires to emphasize. Occasionally some of the illustrations could be dispensed with; for instance, in the nine pages on blood pressure there are ten illustrations showing six different instruments. The greater part of the book deals with the thorax and abdomen; but there are also chapters on examination of the head, neck and extremities, as well as a brief discussion of some of the more important points in the examination of the nervous system.

TUBERCULOSIS AND HOW TO COMBAT IT—A Book for the Patient and His Friends. By FRANCIS M. POTTENGER, M.D., LL.D., Price $2. St. Louis: C. V. Mosby Co., 1921.

THIS little volume of 270 pages is one of the many books recently put on the market to educate the people, and particularly the tuberculous patient. While the reading matter is presented in attractive form, it must be admitted that the book is written in a far too scientific style to be comprehended by the majority of tuberculous patients. Those physicians who have worked among the consumptive poor recognize that the simplest phraseology and the plainest words must be used in dealing with the majority of cases. "Adaptability of organisms," "alkalinity of tissue reduced by exercise," "kinds of bacillus," "calories," "circulatory type of tuberculosis," "emotions and insomnia," "heartbeat governed by oxygen," "metabolism and body heat," "neurasthenic type," "toxemia and temperature," "tuberculin natural stimulus to healing," "weather and metabolism," are some of the expressions taken at random from the index. They are far too scientific for popular reading. Chapter 15, treating on tuberculin, is one which should not be found in a book intended for the laity. Dr. Pottenger's statement that the administration of tuberculin will add to the patient's chances of cure by at least 20 per cent, and in some cases more, is one which the reviewer thinks will not be subscribed to by many American phthisiotherapeutists. The chapters on open air treatment, symptoms, and hygiene in general are excellent, but written in a manner that they will only be useful to highly intelligent patients. The chapter on marriage is particularly good and timely. If the book is intended for the average patient it is too large, too scientific, and too expensive; if it is for the intelligent and well-to-do patient at home, in a health resort, or in a sanatorium, it will prove interesting reading matter providing it does not lead to too much self contemplation.

A PRACTICAL TREATISE ON DISEASES OF THE SKIN. For the Use of Students and Practitioners. By OLIVER S. ORMSBY, M.D., Professor and Head of the Department of Skin and Venereal Diseases, Rush Medical College (in Affiliation with the University of Chicago); Dermatologist to the Presbyterian, Saint Anthony's and West Suburban Hospitals, and the Home for Destitute Crippled Children; Consulting Dermatologist to the Orphan Asylum of the City of Chicago; Member of the American Dermatological Association and of the Congress of American Physicians and Surgeons; Corresponding Member of the Section of Dermatology of the Royal Society of Medicine, London. Second Edition, thoroughly revised. Illustrated with 445 Engravings and 4 Plates in Colors and Monochrome. Price $10. Philadelphia and New York: Lea and Febiger, 1921.

THIS book consists of two parts. The first hundred pages is devoted to a consideration of the general anatomy and physiology of the skin, general symptomatology, etiology, pathology, diagnosis, prognosis, and therapeutics. For the student, this is probably the most important part of the book and should certainly be studied before the discussion of the various diseases of the skin is entered upon. In the chapter on general diagnosis there is included an account of the various tuberculin tests, the Wassermann reaction, and the luetin test. The bulk of the book (about one thousand pages) is given over to the diseases of the skin; and the general arrangement and classification is the one which has been in use for the last half century. On questions of diagnosis and treatment, the author has brought his book into line with the latest teachings. An important feature is the bibliography which, while brief, is well selected and included references to papers which give a more complete bibliography. In a subsequent revision attention should be given to the prescriptions many of which might be improved in language; the mixture of English, Latin and near-Latin is not what we have a right to expect in a book of this class. The illustrations are adequate, and the book is well printed.

ASMA BRONCHIALE. By Prof. CESARE FRUGONI. Salo: Gio Devoti, 1921.

THIS brochure of 88 pages comprises sections on etiology, pathological anatomy, and symptomatology and therapy. In the chapter on etiology we find sections on bronchial asthma, hay fever, endocrinous asthma and asthma in the tuberculous. Under treatment are sections on opotherapy, desensibilization, symptomatic treatment in the interval and management of the paroxysms.

SKILOPERFRAKTURER ET BIDRAG TIL STUDIET AV BENBRUDDENES MEKANIK By OLAV USLAND. Kristiania: Johannes Bjornstad, 1921.

THIS brochure was originally issued as a supplement to the *Norsk Magazin for Laegevidenskaben*. It is also one of a series of communications from the Akers Hospital, service of Professor Christenson. It is a valuable monograph on the fractures to which ski runners are exposed, with a general discussion on the mechanism of fractures. The 31 cases of fracture from skiing, about which the book is written show a great variety of injury involving the bones of the upper and lower extremities and including several special types, as spiral and torsion fractures of the long bones, supracondyloid fractures, separation of epiphyses, etc., etc. The subject is affiliated with that of fractures of snow-shoe runners. According to the bibliography there is very little literature on these subjects in the English language which is the more strange because all such injuries are included under "sport" fractures, and the English speaking peoples are more inclined toward rough sports than any others.

Society Reports.

SOUTHERN MEDICAL ASSOCIATION.

Fifteenth Annual Meeting, Held at Hot Springs, Arkansas, November 14, 15, 16, and 17, 1921.

THE PRESIDENT, DR. JERE L. CROOK OF JACKSON, TENNESSEE, IN THE CHAIR.

(*Concluded from page 40.*)

Observations on the Use of the Copper Filter in the Roentgen Treatment of Deep-Seated Malignancies.—Dr. THOMAS A. GROOVER of Washington, D. C., recommended primarily a single series of roentgen treatments in accordance with a technique not less intensive than that set forth, and that the question of surgical intervention be deferred for a period of approximately two months in cancer of the breast. He believed that by pursuing such a course the following advantages would accrue: (1) The actual volume of cancer tissue would be greatly lessened, and would in some cases disappear entirely so far as could be determined by physical examination. (2) The danger of cancer dissemination incident to surgical trauma would be lessened. (3) A number of inoperable and borderline cases would become definitely operable. It was realized that the danger of operative delay in malignant disease was so thoroughly ingrained in the medical mind that the course proposed would meet with general disapproval, but he believed that a more intimate knowledge of what could be accomplished by efficient radiotherapy would result in a changed point of view.

Some Observations on the Radical Mastoid Operation.—Dr. JOHN H. FOSTER of Houston, Texas, said the reasons for the infrequent use or abandonment of the radical operation by many men appeared to be embraced under the following heads: (1) The few cases of chronic suppurative otitis media today as compared to the number seen in earlier times. (2) The efficacy of conservative treatment and operations. (3) Unsatisfactory results from the radical operation. This operation had been much abused and often improperly applied. It was not indicated in or devised for acute conditions, except in rare cases; nor was the recurrence of a discharge from an ear at intervals an excuse for this procedure. The doing of a radical operation in a case where a simple mastoid was all that was indicated was almost criminal. On the other hand, he emphasized the belief that this operation was one of the most valuable surgical procedures at our command, and that we should be equally culpable in allowing without a protest a patient to subject himself to the danger incident to a chronic involvement of the bone of the attic and mastoid when this could be obviated by this operation.

The Value of Blood Chemistry to the Surgeon.—Dr. WILLIAM H. BAILEY of Oklahoma City stated that the glucose tolerance test had been shown to be of considerable assistance in establishing the diagnosis of cancer, especially of gastrointestinal carcinoma, when the other conditions that gave a similar blood sugar curve had been eliminated. Ether should not be the anesthetic of choice when the patient was found to show an acidosis by a low carbon dioxide combining power of his blood plasma. In gastrointestinal cases showing a starvation acidosis, a two-stage operation might well be considered. A poorly functioning organ was to be feared more as a factor bearing on the operative risk of the patient than a diseased organ that was doing its work satisfactorily. Many deficient metabolic processes of the body might ultimately affect the functional ability of the kidneys. No one test for kidney function should be used to the exclusion of all others. Blood chemical tests, like all other laboratory procedures, must be considered only as additional clinical evidence and their value determined by weighing them with all the data available. A phenolsulphonephthalein output of over 75 per cent. in two hours might be a sign of lessened kidney function. A low phenolsulphonephthalein result was not always an indication of a serious kidney impairment, especially when the blood retention products were not found to be excessively high. A high blood urea content was probably always an indication of lessened kidney function, regardless of the results of the other tests. Satisfactory results could not be expected from these tests if their performance be left to some one not thoroughly conversant with the chemical procedures involved. The estimation of blood creatinine was the most valuable prognostic sign we had in cases of renal deficiency. The slight delay caused by these preoperative studies of the patient would not be a detrimental factor in lessening the patient's chances for recovery in the majority of operative cases. Blood chemistry was of special value in cases of hypertrophied prostate and other mechanical chronic obstruction to the outflow of urine. We should strive to attain the ideal, when every operative patient would be carefully studied by clinical and laboratory methods to accurately ascertain his "surgical risk" before operation, as then that epoch of "physiological surgery" would become truly an established fact.

Clinical Significance of Abdominal Adhesions.—Drs. JULIUS FRIEDENWALD and THEODORE H. MORRISON of Baltimore stated that the diagnosis of pelvic adhesions could usually be best determined by means of pelvic and rectal examinations. The great difficulties frequently encountered in the diagnosis of abdominal adhesions, and the importance of utilizing every available diagnostic measure in order that correct conclusions might be reached; the institution of prophylactic measures, such as the avoidance of unnecessary trauma during operative procedures, and the early stimulation of peristalsis following operation, and in the treatment of these affections, surgical intervention was indicated only after all other possible means had been exhausted, and then only when the symptoms were very severe and disabling, or in the presence of obstructive signs, were points to be emphasized.

Gastroptosis.—Drs. SEALE HARRIS and J. P. CHAPMAN of Birmingham, Ala., stated that in a series of 500 patients studied by them during the past eighteen months *x*-ray examinations in the standing position showed in 278 (55.6 per cent.) that the lower border of the stomach was more than two inches below the umbilicus. These were all adult white patients, most of them native Alabamians, though a few were from Mississippi, Tennessee, Georgia, and Florida. The ancestral lines of the great majority of whites in these States came from England, Scotland, and the north of Ireland, and they conformed to the physical characteristics of the English and Scotch, who were apt to be tall and slender, though hardy races physically. The operation of fixation of the stomach for gastroptosis was mentioned only to be condemned as irrational, meddlesome surgery. The stomach was a very mobile organ and no part of it should ever be fixed as was the effect in all the various types of gastropexies proposed for gastroptosis. *X*-ray examinations by many different observers showed that the operation did not permanently elevate the stomach, and many cases had been reported in which the patient was in worse condition after the operation than they were before they were subjected to an operation which was not without serious danger to life. Their view that gastropexy was never a justifiable operation had been so pronounced that they sent questionnaires to a number of prominent surgeons and gastroenterologists asking their opinion as to the merits of gastropexy. Replies were received from all but two, and without exception they condemned the operation.

Further Observations of Lamblia Intestinalis Infestation and Its Treatment.—Dr. SIDNEY K. SIMON of New Orleans stated that the eradication of giardia infection, once it had become firmly intrenched in the intestinal tract, had proved in the past a signally unsuccessful undertaking. All kinds of so-called intestinal disinfectants had been employed, without effect upon the organisms. Both ipecac and emetine were devoid of influence over this type of intestinal protozoa. In the two cases reported by him last spring transduodenal lavage with jutte solution was given a thorough tryout. In one case the cysts promptly disappeared from the stools, but control had been lacking in determining the permanency of this effect. In the other case the results proved disappointing. Yakimoff in 1917 was the first to suggest the use of arsphenamine in the treatment of giardia infection. He employed this drug experimentally in mice, using 1 c.c. for 20

grams body weight. Two years later Carr and Chandler made use of this preparation for the first time in the human individual for the purpose of eradicating *Giardia intestinalis* infection. Their results proved so promising that he had made free use of the drug in six of the cases reported. In one case, that of a five year old girl, the drug was introduced directly into the intestinal tract through the duodenal tube, while in the other cases the intravenous route was selected. In each instance he found a prompt disappearance of the cysts from the stools, and as far as he had been able to ascertain subsequently no further trace of the infection had been made out.

Lamblia Intestinalis with Report of Cases.—Dr. J. E. KNIGHTON of Shreveport said that *Lamblia intestinalis* invaded the bile ducts and gall bladder. This had been observed by Smithies in cases of gall-bladder disease that were treated surgically. Lamblia might be capable of producing cholecystitis or might have been only a complicating factor in the cases reported. Lamblia infection was not necessarily associated with diarrhea. Only one of the three cases mentioned had at any time been troubled with a persistent diarrhea and this was many years before the onset of the present trouble. Transduodenal lavage or duodeno-biliary drainage gave only temporary relief.

My Observations on Hepatic Extract as a Remedial Agent.—Dr. A. L. LEVIN of New Orleans gave his impressions with regard to hepatic extract as follows: (1) It was a useful agent to stimulate liver function unless it was beyond repair. (2) It must be used for a long period until definite good results had been obtained. (3) It was of value in conjunction with nonsurgical drainage, but had no power to influence pancreatic pathology. (4) It could be used as a diagnostic agent to determine the hepatic origin of the trouble. (5) Liver enlargements due to biliary stasis could be diminished in size in a reasonably short period if used in conjunction with nonsurgical drainage; this included acute catarrhal jaundice. (6) The injection did not give rise to any unpleasant reactions, local or systemic. (7) He was not certain as to the proper dose.

Diphtheria and Hemolytic Streptococcus Carriers as Shown by Tonsil Section and Growth After Enucleation.—Dr. GEORGE E. ADKINS of Jackson, Miss., stated that one of the most essential things in reducing the prevalence of diphtheria over the country would be the complete removal of tonsils and adenoids or the clearing away of points of chronic focal infection in the upper respiratory tract of all diphtheria carriers (or rather all those cases which gave a positive history) regardless of an examination made by reported swabs. Myocardial and nephritic conditions, as well as hyperthyroidisms, should be dealt with practically in the same manner, for it seemed that they were dependent on a focal infection in which the predominating or chief offender was the hemolytic streptococcus.

The Treatment of Lung Abscess.—Dr. C. O. GIESE of Colorado Springs stated that from 6 to 33 per cent. of all cases of lung abscess recovered spontaneously. If spontaneous recovery did not occur within eight weeks, some type of operative procedure should be considered. The type of operation to be advised depended on the location of the suppurative process and the pathology present. Bronchoscopy, artificial pneumothorax, thoracotomy, extensive rib resections and lobectomy were of value, and should be employed in suitable cases. The artificial pneumothorax apparatus afforded a simple and reliable method of determining the presence or absence of pleural adhesions, and over how large an area these adhesions existed.

Abscess of the Lung.—Dr. H. W. LYMAN of St. Louis said that in foreign body cases preventive measures consisted in the discovery and prompt removal of the offending substance, through the bronchoscope, and in the exclusion of an unsuspected foreign body in obscure pulmonary conditions. To prevent cases occurring after operations in the upper air passages, precautions should begin with a careful physical examination, and, except for very urgent reasons, the patient not operated on unless in good condition. Tuberculosis, alcoholism, and diabetes added materially to the danger of this complication. Tonsillectomy in an adult must not be regarded as a minor operation. The use of ether should be avoided in these operations, if possible, but, if used, the anesthetic should be light, an efficient suction apparatus employed to keep the throat as clear of blood and detritus as possible, the patient placed in some position in which the blood could not flow down the trachea, and, after the operation, be kept on the side or prone until consciousness was thoroughly regained. He believed if a general anesthetic was necessary, nitrous oxide was safer than any other in operations on the nose and throat. The question of giving hypodermic injections of morphine, or drugs of similar character, before the operation must be carefully considered because of the fact that they abolished the cough reflex and thus added to the possibility of inspiring infective material. Patients should not be operated on too soon after an attack of acute tonsillitis. At least two weeks ought to elapse before any operative interference was undertaken. The bleeding following tonsillectomy would nearly always cease if left undisturbed for a few minutes. Consequently, any swabbing or manipulation of the tonsillar fossæ should be avoided, if possible, to prevent the dislodging of any thrombi which had formed in the cut veins. The operative technique should be so planned as to minimize the possibility of the inspiration of infective material into the bronchi and the dislodging of venous thrombi from the site of the operation. The forcing of fluids should be a routine measure for the rapid elimination of any toxemia which might ensue.

External Deformities of the Nose and Their Correction by the Intranasal Route.—Dr. SIDNEY ISRAEL of Houston, Texas, stated that in the application of surgical art in the correction of external defects of the nose several requisites or cardinal points were to be observed: (1) There should be no external or visible scar, if it was possible to avoid. (2) Whatever surgical step was taken it must be corrective and accurate and adapted to the individual face. (3) We should have a clear understanding of the deformity and the necessary measures for correction, together with the anatomical and artistic ideal to be approached. (4) Our technique should be mechanically and aseptically as far above criticism as it was possible to acquire. As a result of investigation carried out to determine the most satisfactory transplant for the correction of saddle-nose deformities, he thought that cartilage offered the best results, and was far superior to bone or any foreign substance, such as celluloid. He emphasized the importance of postoperative care, for in no class of work was this more exacting. The reaction locally was negligible and promptly subsided, and, strange as it might seem, these patients suffered practically no pain and little or no discomfort, although it was required that they wear the proper splint, suited to the individual case, for a short period. That the rhinologist should be the one best suited for this special field of surgery, owing to his knowledge of the part, was apparent, provided he possessed the mechanical skill and appreciation of the proper anatomical ideal to be approached, for these cases were individually a distinct mechanical and artistic problem within themselves.

The Management of Tuberculous Laryngitis.—Dr. WILLIAM MULLINS of Colorado Springs said that treatment should begin with careful attention to the nose and throat, as a great many of these patients were in bed on account of temperature, and did not take care of their secretions well. The effects of a deviated septum or of infection of the sinuses or tonsils had a definite influence on the general physical welfare, but the question of the appropriate time to operate for the relief of these conditions must be given the most careful consideration in pulmonary tuberculosis. Diseased tonsils might be largely responsible for a persistent temperature, but such a conclusion could only be arrived at after the internist had satisfied himself that the chest condition was not solely responsible. Cough would irritate the larynx and an irritated larynx or pharynx would perpetuate and aggravate the cough. Intratracheal injections of a soothing oil he had found of great service in breaking up this vicious circle. The laryngeal syringe in preference to the swab was most satisfactory, as it avoided trauma and gagging and permitted covering the whole laryngeal surface as well as the trachea. On the other hand, one might be able to make no progress with an actively diseased larynx until the cough and profuse secretion improved, as might

happen after an artificial pneumothorax. A slight verrucous thickening in the posterior laryngeal wall often gave the scratchy feeling of a foreign body. This annoyance would usually disappear after several light applications of the galvano-cautery. Trichloracetic acid would produce the same results, but was often followed by a temporary spasm. Infiltrations would usually respond to rest and mild palliatives, such as weak iodine solutions and argyrol, but edematous swellings would probably require deep cautery puncture. Localized ulcerations responded best to cauterization of sufficient extent to produce a slight slough, best done by a large cautery point. Tracheotomy must be done in some cases and when it became apparent that this was inevitable, give the patient the benefit of this procedure early. Delay resulted not only in unnecessary suffering, but, by prolonging the bad effect of the stenosis, might prevent or greatly retard any subsequent improvement.

X-Ray Diagnosis of Aortitis.—Drs. THOMPSON FRAZER and JOHN D. MACRAE of Asheville, N. C., said that by examining many different types of normal individuals they formed a conception of what a normal heart should look ike. There would be wide variations within the normal, but the different types would show the same characteristic curves for the left border of the arch of the aorta (the aortic semicircle), the pulmonary artery, the left auricle and the left ventricle on the left of the midline of the chest, while on the right they generally saw the curve representing the ascending aorta and the right auricle. In aortitis and aneurysm these contours were changed. Saccular aneurysms were usually recognized without difficulty; those of the ascending portion lay chiefly to the right of the midline; those of the transverse arch cast shadows in the upper mediastinum which extended to the right or left, depending on which portion of the arch was involved, while aneurysms affecting the descending portion of the arch lay to the left of the midline. Less spectacular than in the cases just discussed, but perhaps more important, because they were so commonly overlooked, were those cases of aortitis with dilatation that were not usually classified as aneurysms. Many of these cases passed from one physician to another, complaining of fatigue, dyspnea and oppression in the chest, and while these symptoms might lead to a tentative diagnosis of heart disease, the actual condition was frequently not recognized until an *x*-ray examination was made. This type of aortal disease was most commonly found in the ascending arch; quite often the transverse portion was involved as well; sometimes there was dilatation with elongation of the entire arch. The dilatation might be slight or well marked.

On the Tolerance of Children for Digitalis.—Drs. HUGH MCCULLOCH and WAYNE A. RUPE of St. Louis stated that the method of administering massive doses of digitalis to children should be the same in detail as for adults. The use of massive doses to children was entirely practical, and under proper supervision possessed no source of danger, That amount of digitalis necessary to produce clinical improvement coincided with the amount necessary to produce vomiting and a fall in heart rate. These two phenomena might be taken as criterion that an optimum therapeutic effect had been obtained. Children with heart disease required an amount of digitalis per kilo of body weight, which was about 50 per cent. greater than would be required for adults. There were two indications for the use of digitalis in children. First, those who were suffering from heart disease and who were in a state of chronic cardiac failure. Second, those who had a regular rapid heart rate when that heart rate could not be slowed by other measures. Massive doses of digitalis were contraindicated in two groups of children with heart disease. First, those who had an acute infectious or toxic myocarditis; second, those who were suffering from acute cardiac failure with hearts that were overloaded.

Active Immunization Against Diphtheria.—Dr. ALBERT SNEDES ROOT of Raleigh, N. C., asked whether each pediatrician could not, or rather would not, see that active immunization was carried out in the schools of his city, whether this be large or small? In many cases he would be the only one who could properly perform and interpret the Schick test and hence the only one available for the work. If the work was thoroughly done and the school population largely immunized during the first year, the Schick test might be omitted thereafter and each incoming class immunized with toxin-antitoxin. This could be done by a nurse from his city's board of health. Park found that immunity was established in 80 per cent. of children who showed positive Schick test three months after the last dose of toxin-antitoxin and 90 per cent. six months after the last dose. It would be best to retest pupils who had received the treatment at the end of six months to be sure that their immunity had been established, and if not an additional dose of toxin-antitoxin given. This was not an absolute essential to the accomplishment of the work. Would not a concentrated effort on the part either of the pediatric society of each State, or if such an organization did not exist on the part of individual pediatrists in a State, to bring into reality through its respective State board of health such a plan as that which was proving so effective in North Carolina in the active immunization of the preschool child?

A Further Report of the Classification of Birth Paralyses as Endocrines.—Dr. LEE BEN CLARKE of Atlanta said that many cases showing mental or physical deficiency and birth paralysis were due to disordered functions of the ductless glands. No case showing mental or physical deficiency should be dismissed as hopeless until it had been definitely established that it did not belong to this group. It was probable that few, if any, infants who survived had been permanently injured at birth, and that the defectivity was entirely intrauterine. Early recognition followed by early and thorough treatment was necessary if the best results were to be obtained. *X*-ray studies of the sella turcica and complete study of the spinal fluid, including Wassermann, were invaluable in the differential diagnosis, since surgical conditions, *i. e.* pituitary tumors, etc., and syphilis must be excluded.

Intracranial Hemorrhage in the Newborn; Case Report.—Dr. EUGENE ROSAMOND of Memphis said the point of interest in this case was the occurrence of an intracranial hemorrhage in a cesarean baby, the absence of all external bleeding, the severity of the convulsions, their duration of thirty-six hours before efforts to stop the hemorrhage was made, and the prompt cessation of the convulsions when the bleeding was stopped. Thirteen other cases of intracranial hemorrhage seen in the past twelve months all responded promptly to blood therapy. Several did not get beyond the stage of pallor and restlessness, when the coagulation time was taken, and the true condition discovered. Only six cases showed external bleeding. Since a routine determination of the blood coagulability would reduce the mortality of the newborn practically 50 per cent., and, furthermore, since it would probably prevent a large number of the cases we now saw of birth palsies, it was well worth the extra time and care it would take to make this a universal, routine procedure.

Infections of the Urinary Tract, with Report of 400 Cases.—Dr. EDWARD CLAY MITCHELL of Memphis stated that a routine examination of the urine should be made in all acute febrile conditions in children, as early recognition and prompt treatment was of first importance. There was no specific treatment. Each case should be treated as an individual. Large amounts of fluid should be given in all cases. Search for all foci of infection. The alkaline treatment had succeeded best in his series, but was by no means infallible. Intestinal antiseptics, pelvic lavage and vaccines were of secondary value, and should not be discarded where the other methods had been tried and found valueless.

Direct Exposure to Tuberculosis in Infancy and Childhood and Its Relation to Manifest Pulmonary Tuberculosis in the Adult.—Drs. W. M. TAYLOR and L. J. MOORMAN of Oklahoma City said that childhood infection was almost universal. Heavy and moderate infection, especially in the first four or five years of life, depended upon the history of direct contact. After five years of age many cases showed heavy or moderate infection without a history of direct contact. This increase in the number of cases showing heavy and moderate infection after five years of age without a history of contact would suggest that massive or gross infection was not due to a single large dose of tubercle bacilli, but rather the cumulative effect of repeated small

doses. The *x*-ray was perhaps the most valuable method of determining the degree or extent of infection, but should be employed in the diagnosis of clinical tuberculosis only in connection with a thorough study of the history and a complete physical examination. There seemed to be a definite relation between childhood exposure and manifest pulmonary tuberculosis in the adult as shown by the fact that routine history taking showed childhood exposure in 62 per cent. of their 200 adult cases. This preponderance of childhood exposure in connection with adult cases, together with Bushnell's teaching that exogenous reinfection in the adult could not take place only in the presence of such a large infecting dose as to make it rarely, if ever, possible, and that the curve of tuberculosis morbidity rose with the increase of want and hardships, and fell with economic physical and moral betterment, strongly suggested reinfection from within rather than from without. They believed there must be many periods of mild tubercle toxemia between the date of infection and the discovery of clinical disease, and that many cases of so-called malnutrition, nervous instability, malaria, anemia, undetermined fever, etc., might be the result of such toxemia. Finally, since there seemed to be a definite relation between childhood exposure and adult tuberculosis, and that there were in all probability many vague symptoms in childhood which arose from tubercle toxemia, after having done what we could to prevent early contact with open cases, we should employ every possible means to determine the degree of infection, especially in contact cases, in order that those showing heavy or even moderate infection might have special observation and supervision with the purpose of safeguarding the child by improving the environment and by the early recognition of symptoms and signs, should they develop.

Infectious Diarrhea in Young Children.—Dr. RALPH C. SPENCE of Dallas, Texas, stated that these cases of acute diarrhea in infants and young children, whose onset was sudden with fever and prostration, and whose stool showed blood and mucus over a period of several days, were due to one of the two groups of dysentery bacilli, while those cases whose stools did not show blood and mucus were probably not due to the dysentery bacilli. This disease was infectious and strict quarantine precautions should be observed. If this was done the prevalence of this disease in this section of the country would be much decreased, and if correctly diagnosed early and properly treated, the existing high mortality from this disease would be greatly reduced.

Pulsus Alternans; Its Significance and Recognition by Ordinary Clinical Methods.—Dr. RANDOLPH LYONS of New Orleans said that it was obvious that from so small a number of cases no deductions were possible, but he had been impressed by the fact that if blood pressure readings were performed more carefully, bearing in mind the possibility of the presence of pulsus alternans, this symptom would be far more frequently detected by physicians in general practice than it was at present. This had been his own experience during the past year. Owing to the fact that many physicians took graphic records only of cases which showed an irregular cardiac action, the presence of pulsus alternans frequently eluded them, for here the pulse might be regular with little or no acceleration. Furthermore, pulsus alternans might be very transient, rendering the taking of graphic records impractical in many cases. The careful use of the auscultatory blood pressure method in all cardiorenal cases, especially accompanied by hypertension, would be of great value in detecting this condition. The error of confusing the regular occurrence of late extra systoles (pulsus bigeminus) with alternation of the pulse was the chief pitfall. It might be possible in a certain proportion of cases to differentiate positively between the two conditions without graphic records. According to White and Lunt, the error of confusing pseudoalternation with true alternation, using the auscultatory blood pressure method, was about once in six times. It was possible that this error might be further reduced if one bore the following points in mind: (1) In pulsus alternans, upon listening over the bend of the elbow at the time when all beats were heard, the sounds were perfectly regular, whereas, according to Mackenzie, in the cases of pulsus bigeminus there was always a delay after the weaker beat. (2) In pulsus alternans, on auscultating the heart, it was extremely rare to note any difference in intensity of the strong and weaker beats, while in the case of regular premature contractions the premature beats were apt to be less intense. Undoubtedly, errors would creep into any of the clinical blood pressure methods, and even admitting that a mistake might be made in one out of six times, this percentage was not so great as to rob it of value, and should act as a stimulus to check such observations by graphic tracings. The auscultatory blood pressure method would, in a few instances, detect a slight alternation where tracings failed to reveal it. The delicacy of the method was demonstrated by the fact that an alternation of only 5 mm. of Hg. could be detected. Furthermore, in two patients it was possible to recognize the diastolic pressure of the alternate strong and weak beats and thus determine their pulse pressure independently. The importance of detecting pulsus alternans was very generally appreciated, but the gravity of this ill-omened symptom depended upon its persistence and association with other signs of cardiorenal insufficiency. Finally, its presence demanded the removal of any exciting cause, as physical strain, infections, and toxemias, where possible, and was, in general, an indication for digitalis therapy.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held October 13, 1921.

DR. MINER C. HILL IN THE CHAIR.

Ritter's Disease with a Fatal Termination following Tonsillectomy.—Dr. JAMES HOYT KERLEY reported this case, in which he said that Ritter's disease or exfoliative dermatitis, strictly speaking and as described by the author, was a disease of the first few weeks of life. The following case, however, so strongly resembled in its symptomatology the above mentioned disease that he had placed it under that terminology. Ritter's disease consisted primarily and essentially of inflammation of the skin with exfoliation, the formation of vesicles being only a secondary symptom. The disease usually began on the face, at the angles of the mouth, and under the chin, but might begin on the abdomen or genitals. The first change was a bright diffuse reddening and swelling of the skin, which gradually spread over the entire body, resembling erysipelas at this stage. The skin of the affected part looked thicker and more transparent as though the horny layer had been swollen and macerated by long applied warm and moist compresses. The epidermis became loosened from the corium so that there was a vesicular bulging of the former. Large areas of superficial skin appeared to be soaked in serous fluid and a condition of epidermolysis and exfoliation followed. The course of the disease varied. It might spread rapidly over the entire body so that in a few days the skin might hang in shreds, exposing almost everywhere a very red and livid corium. Infants so affected died within a few days, or the course might be slower, the disease remaining at its height for over a week, then subsiding slowly and ending in recovery. It was difficult to separate this disease from acute pemphigus. Ritter's disease, however, was marked more by exfoliation and pemphigus by exudation. The latter disease did not begin with an erythema and its vesicles were outlined by a well defined border, while in dermatitis exfoliativa the inflammatory borders were rarely round, but were ragged and irregular in outline. The clinical history of the disease justified its being considered of a septic nature. Staphylococci were usually found in the skin and generally in the blood also. Although we might not be sure where the infection entered there was every probability that bacterial processes played the most important part in exfoliative dermatitis.

The present case was that of a boy 2 years old who had had his tonsils and adenoids removed four weeks before coming under observation. The operation was followed by otitis media. The temperature during this time was of a septic type, ranging from 104° F. to normal. On physical examination the child appeared very

septic and in a moribund condition. The eyes were glazed. The bases of the tonsils were red and swollen; ears perforated, but no sign of mastoid involvement; ulcerative stomatitis was present. The heart sounds were faint; lungs negative; spleen and liver not felt. About the mouth and chin were areas of coppery discoloration. Patches of livid eruption were present on the face and scalp. On both shoulders were large pemphigoid areas which had ruptured. Dark brown erythematous lesions were on the arms, trunk, and extremities, with remnants of blebs on the trunk. Smaller hemorrhagic patches, livid in color and bluish, were over the temples and on the body. The urine showed innumerable pus cells and a heavy trace of albumin. The child was too ill for a blood culture. The temperature was 101°. The diagnosis of dermatitis exfoliativa (Ritter's disease) was made. The history and physical findings of this case pointed strongly to a systemic hematogenous sepsis resulting probably from absorption of bacteria or toxins from the operative wound. The discoloration of the face, coppery colored, the livid areas on the face, head and body, and the pemphigoid condition of the skin strongly resembled what was seen in the new born as dermatitis exfoliativa (Ritter's disease).

Dr. HENRY KOPLIK stated that he had seen this patient. It was a case of the kind he had seen in infants, although this child was two years of age. The conditions as described by Ritter was really a septic condition which was observed at the foundling hospital in Prague. Epstein, the chief of the service, later made the statement that this disease was gradually disappearing from the institution. In other words, that as hygienic conditions improved Ritter's disease went out. The name Ritter's disease should be limited to the condition described by Ritter, but Dr. Kerley's case so closely resembled Ritter's disease, and followed tonsilectomy and otitis media, that it seemed proper to give it this name. It was the only case of the kind he had seen in a child of this age.

Dr. MINER C. HILL asked Dr. Koplik whether he had seen any of these cases get well.

Dr. KOPLIK replied that about 50 per cent of the cases among the new born recovered.

When Shall the Membrana Tympani be Incised, and When is Reincision Indicated?—Dr. WALTER LESTER CARR presented this paper, in which he urged that a routine examination of ears and throat be made in all infectious diseases, and in every condition where there was a question as to the cause of irregular high temperature with or without local pain in the ear. A child might have pain without a rise of temperature, or at most a degree above normal, or there might be restlessness or irritabiliity without temperature and pain. Examination must be made with a good reflected light after the external canal had been wiped clean. The necessity for this examination was shown by the fact that every physician was liable to be chagrined by the report that "the ear burst in the night." He had had such an accident in children with acute poliomyelitis and in bronchitis when he had not anticipated it. If the tympanum was found to be red and bulging the decision to open the drum should be made at once, especially if the child had a rise in temperature and pain. When there was congestion and bulging, as was seen in scarlet fever, the advisability of myringotomy might be determined, in part, by the state of the pharyngeal tissue. If the structures of the tonsils and pharynx were reddened and swollen so that there was blocking of the outlet of the Eustachian tubes an incision of the drum might be advisable. It might be possible to abort such a condition by the use of adrenalin solution, 1 part to 4 or 5 of normal saline solution instilled into the nares so that it came in contact with the swollen Eustachian tubes. An incision of the drum was not, however, the whole treatment. In addition to irrigations of the external auditory canal, local applications to the pharynx and tonsils of argyrol or a similar preparation were essential to get the best results of drainage from the cavity of the middle ear. Where there was an acute infection of the middle ear, as in pneumonia, tonsillitis, influenza, etc., the pediatrician was almost always willing to incise the drum or have it done by an otologist, as he realized that to allow the infectious process to damage the structure of the middle ear would cause changes in the drum membrane and ossicular joints and might allow the disease to extend to the mastoid process. Although a patient could not be protected against a mastoid disease which might be occasioned by a systemic infection it was possible to give some drainage through the external meatus. In children who had an earache associated with mild catarrh, nasopharyngitis, hay fever, or gastrointestinal disturbances, decision to open the drum should be determined by the symptoms of the individual child. One who was nervous and high strung and who had pain and slight elevation of temperature might be better for having the ear drum incised even when there was not much bulging or congestion. Many nervous children got comfort from the application of local heat, or argyrol to the nasopharynx, and from instillations of warm boric acid solutions into the ear. Medicinal agents such as calomel were of service, and small doses of codeine, antipyrin, sodium bromide, and belladonna gave comfort. The instillation of warm oil was not helpful and might be detrimental. The writer had found some benefit when novocaine and adrenalin solutions had been dropped on a congested tympanic membrane, but he had not depended upon these agents alone, and was unable to state how useful they were. In his experience patients who had relief only when chloroform vapor was blown into the ear required incision. At the New York Eye and Ear Infirmary the organisms found in smears after incision of the drum were streptococci, pneumococci of the different groups, Friedlander's bacillus, staphylococci, and *B. catarrhalis*. When cultures were made care must be taken in method and media or staphylococci might overgrow other organisms and give rise to a faulty interpretation. Recision might be required if a primary incision had not been free enough for drainage and when infection and swelling of the Eustachian canal blocked the way to the pharynx. Reincision was indicated particularly when there was sagging of the wall of the external auditory canal, even if no other symptoms of mastoid disease were present. Reincision must be made if the tympanum showed the same condition that necessitated primary operation, namely, pain, bulging, and elevation of temperature. Reincision might be indicated in children of poor vitality where drainage from the middle ear was imperfect even after removal of hypertrophied tonsils and adenoids. In all children in whom an incision had to be made in the drum membrane there was no excuse for omitting the removal of tonsils and adenoids even when these structures did not show a great degree of infection and obstruction. Children of low vitality needed also hygienic and tonic treatment. There were cases in which mastoid symptoms were present in which the otologist and pediatrist would have to decide whether the incision should be made or the mastoid cells excenterated.

Dr. JOHN R. PAGE expressed the opinion that Dr. Carr had stated the situation very well indeed from the standpoint of the otologist and that he had no disagreement with the views expressed. He had been led to believe that most pediatricians were much less radical, if those statements were considered radical. The otologist and the pediatrician disagreed on this question for the same reason that they did not always agree as to when it was best to open the mastoid. The ear man from his association with complicated cases had the danger of delay impressed upon him so forcibly that he would rather err on the safe side than open too late, feeling, as he did, that harm practically never resulted from an early paracentesis. The children's man doubted this, and advanced as an argument against it the danger of infection from outside, having in mind when he did, not a paracentesis but a free incision for drainage, a U-shaped incision, etc., so much talked about but so seldom performed, while the ear man had not this in mind at all. If he saw evidence of marked involvement, with infection, he made a free incision from below upward in the posterior part of the membrane and evacuated the contents; but if he found the membrane retracted and reddened, with the patient in pain he did a paracentesis (nothing more) with a small knife, which was sufficient to relieve the pain and let any extravasated serum escape that might be present. The early cases of otitis media had a negative pressure in the tympanum and in some cases the

pain was as acute at this stage as it was in others from fluid under pressure. Just as a dry cup produced a hyperemia of the skin and, if its use was prolonged, hemorrhage and exudation, so would negative pressure in the tympanum cause swelling and congestion of the mucous lining and extravasation into the cavity. A minute opening into such a drum relieved the situation immediately and almost invariably. The chance of carrying infection through a thin membrane into such an air chamber with a sterile knife was very slight and not to be compared with the danger of lumbar puncture, so often considered harmless. Of course, if a U-shaped flap was going to be made and fluid syringed through into the throat, as some thought advisable, a careful man would rather take the chances with nature than to submit the child to such heroic treatment. In any case in which the membrane could be seen through a speculum, the canal could be cleansed and filled with alcohol and the drum entered with the point of a small sterile knife with no more fear of outside infection than in a lumbar puncture, and it was surprising to learn that beyond the knife and the speculum these precautions were not always regarded as necessary by some who performed myringotomies. In cases in which the canal was so swollen that the membrane could hardly be seen and the knife had to be passed in contact with the posterior wall as a guide and the drum opened blindly, then of course there was a greater chance for infection, but these were cases in which the process was usually well established and there was little doubt of the necessity for incision. Still, even where the swelling was marked, packing the canal with cotton moistened with alcohol and allowing it to remain in place for five minutes would squeeze out the edema and give a good view more often than was realized by many. A paracentesis or myringotomy could not be performed satisfactorily with the infant held in the upright position, for in that position one could not see well what he was doing nor properly cleanse the canal; if the child when properly swathed could not be held still on the table, it could be given a little whiff of chloroform unless there was some very positive contraindication. Dr. Page said he did not wish to be understood as saying that he opened every drum membrane that he met. On the contrary, he frequently advised waiting, but he kept in close touch with such patients and would not allow the ear to be irrigated with hot water so as to render it impossible to tell how much the increased redness was due to hot water at 110° F. It was fortunate for patients that the directions for hot irrigations were usually so poorly carried out that the water did not reach the drum, for it was likely to make them dizzy and seasick from the caloric action on the labyrinth. The canals, however, were usually swollen by it and it created doubt about the membrane itself. A hot water bag masked matters less, and, while it did not divert the patient to the same extent, it probably afforded as much relief. Much relief seemed to be obtained by some patients through intranasal drops of adrenalin, argyrol, etc. Despite the opposition, he felt that he obtained more certain ventilation of the drum and more prompt relief from pain by the small, precise, careful and, as Dr. Gruening used to say, "in my hands," harmless perforation of the drum. In regard to reincision, it might seem necessary a day or two after the first paracentesis, if in an ear in which the infection was well established, the drainage was insufficient and there was some doubt as to whether a proper incision was made to meet the condition in the first place. It could do no harm and it frequently did good; but repeated incisions made simply because the drum bulged were useless in a well-infected ear. A membrane could be cut to ribbons and it would still bulge, not from retention but from swollen mucosa in the region of the additus and from granulations in the tympanum. Dr. Page appealed to children's men in hospital practice to note all running ears in children that had been cured of the various diseases for which they were admitted, and urged that the house physician should stamp on the cards of these patients that they had a purulent otitis media and should be referred by the office to a proper place for observation and treatment. If this were done there would be fewer cases turning up with the membranes sloughed out by prolonged discharge.

Limitations of the Reincision of the Tympanic Membrane.—Dr. SAMUEL J. KOPETZY and Dr. ALFRED A. SCHWARTZ presented this communication from the Otolaryngological Department of Beth Israel Hospital. They stated that, employed early and properly performed, the value of incision of the membrana tympani as a surgical procedure admitted of no discussion. Due to factors other than the establishment of drainage a certain percentage of cases developed into the type of mastoiditis calling for operative interference in spite of early drum incision. In an effort to prevent this development, a great many physicians—and in this class must be included a number of otologists—incised the drum membrane repeatedly. They argued that if it were true that simple incision of the membrana tympani gave complete relief in certain cases of otitis media, then surely in cases in which the disease showed a tendency to spread further than the confines of the middle ear and antrum a second incision might increase the drainage obtained; and so they continued on until perhaps shredding of the drum was accomplished in the vain and illogical effort to drain diseased regions which were out of reach of surgery applied to the middle ear. The writers contended that paracentesis or repeated paracentesis could not prevent or cure operative mastoiditis. Only in young infants could reincision of the drum-head be logically employed, and this because of the rudimentary and undeveloped mastoid process. Bearing in mind this one exception, their contention found further support in a study of the pathology of mastoiditis, the mode of infection and the clinical course of acute purulent otitis media. Did one but visualize the stages and evolution of the pathological lesion in every case as it was presented to him, the chances of misjudging the necessity of repeating incision of the drum-head would be lessened. Too often the clinician did not do this. It was of no avail to repeatedly incise a drum-head to evacuate pus and to attempt to prevent an operation on the mastoid process in the type of case in which the clinical history, bacterial flora and general aspect were such that one was reasonably certain that it fell within the group type termed "hemorrhagic mastoiditis." In this type the infection was not walled off as in the coalescent type, but the dilated blood vessels rapidly carried the infecting organisms throughout the mastoid and, unless the process was promptly and completely checked, even further, into the sinus, meninges and brain. This form had been rightly called the dangerous form of mastoiditis, and its prompt recognition was imperative for the preservation of the patient's life. Yet, strange as it might seem, it was this type that most frequently was overlooked by the attending physician. The patient complained of pain in the ear, and there was a high temperature, 103° or 104° F. Paracentesis was promptly and properly performed, a free incision being made into the membrana tympani. Much to the surprise of the attendants on the case, there was only a slight seropurulent discharge from the middle ear, the temperature had again gone up and the patient was distinctly ill. There might be slight mastoid tenderness, not sufficient to occasion alarm. Another paracentesis was performed; then, perhaps, a day later, another. In the meantime the mastoid infection had continued unchecked, and complications with symptoms referable to the sinus and meninges put in appearance. This picture was not overdrawn, for it had been observed time and time again during the past two years, especially during the recent influenza epidemics. In these cases valuable time had been lost, repeated paracentesis had not prevented the operativemastoiditis, and the patient's life had been greatly endangered. A slight discharge from an incision of the membrana tympani might mean not an insufficient opening, but a virulent infection. In this type of mastoiditis there should be borne in mind another factor, namely, the simultaneous involvement of both middle ear and mastoid where both demanded surgical interference from the onset. In the so-called coalescent type of case, where drainage was profuse and inspection revealed that the incision of the drum-head was adequate, and the pus came away in pulsations, too profuse to be considered as coming from the tympanic cavity, nothing was accomplished by reincising the drum, and other problems than drainage were demanding solution. The fact to be stressed was that the physician should

familiarize himself to a greater extent with the types of acute purulent otitis media and of mastoiditis. Let this knowledge become more general, and agreement upon the surgical procedures to be employed would soon ensue. When, after the delay occasioned by the attempts to cure the mastoid disease by reincisions, the patient finally came to operation, the disease might be far advanced, with marked destruction of the mastoid structure, and the drum might be shredded or practically destroyed. Hearing was markedly impaired in many cases treated by reincision. It had been claimed that the drum membrane was not essential to hearing. Functional tests proved the fallacy of this contention. In a cursory examination of their office records the writers had found as many as eight cases that eventually came to operation after having been previously subjected to three, four, or five paracenteses each before coming under their care; and in some of these all the paracenteses were made during the first seventy-two hours. Not only was mastoiditis not prevented in these cases, but in three septic thrombosis developed, and one died of a suppurative meningitis. A large number of their cases of chronic suppurative otitis media traced their origin to an acute attack where repeated paracenteses were performed. Many were now in such a condition that they could not be cleared without the radical operation. There were others where the drum membrane had healed and the middle ear was dry. The multiple scars were frequently adherent to the middle ear structures and there was loss of mobility of the ossicles, resulting in marked impairment of hearing and tinnitus. It would have been much better in these cases to have drained the antrum from behind or eradicated the disease in the mastoid process and to have prevented the chronic diseases from gaining a foothold. For a simple mastoidectomy should leave the hearing unimpaired and markedly diminish the risk of further complications.

Dr. Miner C. Hill said they had formerly been taught that whenever there was a bulging drum membrane with elevation of temperature and pain the drum membrane should be incised. In children pain was not always manifested, unless it might be by irritability. Again, some drum membranes that required incision were retracted as well as bulging. During the epidemic of influenza he had seen a hundred of these cases of otitis media with slight bulging that cleared up without incision.

Dr. Wendell C. Phillips mentioned two points in connection with the remarks made by Dr. Page and the reader of the first paper in reference to the subject of paracentesis that he said he felt could be brought out in a clearer manner. He regretted that he could not follow Dr. Page in all his contentions. He had been led to believe by long experience that there were two distinct types of middle ear involvement not only in children but in adults. There was one with severe, lancinating pain, which caused a baby to cry out and an adult to say he was suffering considerable pain, temperature and a bulging of the drum membrane. This was the purulent type. The other type was the catarrhal type, in which the symptoms were not marked. It was usually caused by an obstruction; there was negative pressure and a retracted ear drum. One should keep the knife away from this type. In the purulent type the drum membrane was usually red, but not always, and this type should always have paracentesis. Dr. Phillips said that being a teacher he was likely to be arbitrary in what he said; it was his opinion that catarrhal otitis was always catarrhal otitis, and never became purulent, while purulent otitis media was always purulent and never become catarrhal until cured by paracentesis. As a rule purulent cases did not get much relief from repeated paracentesis. If incision did not do its work at first, as a rule it never would do it. By this he did not mean that one should never do a second paracentesis, for all otologists occasionally had to make a second incision to comply with the insistent requests of the family, but in such cases it was simply a postponement of the time when an operation for mastoiditis had to be performed.

Dr. L. E. La Fetra said it always seemed to him the otologists took a very pessimistic view when they saw a bulging drum membrane. He was sure all would agree that if a child had a high temperature and a bulging of the ear drum persisting beyond twenty-four hours, and with these signs increasing, that the drum membrane ought to be incised. But many red, swollen and bulging ear drums cleared up without incision even when the bulging was distinct in all parts of the drum membrane, so that bulging was not an absolute indication for paracentesis; he understood fully the danger of fulminating mastoiditis and its complications. He had had a large experience with otitis media with the mastoid tip involved, and had seen many clear up without incision of the drum, so he could not subscribe to the early incision. If, however, after twenty-four hours the bulging and the temperature had increased, one should not wait any longer because the danger of mastoiditis was so much greater than the danger of simple incision of the drum that no one should hesitate as to which to choose. In regard to second incisions of the drum membrane, he was inclined to agree with the otologists that if one made a free incision the first time, and there was very little discharge, together with a persistence of the symptoms, one must look for trouble in the mastoid. If the incision become small and the discharge persisted reincision was indicated. One thing must be emphasized, that was that in children a vacillating temperature, high leucocyte count and high polymorphonuclear count did not necessarily mean mastoiditis, nor did it mean sinus thrombosis. One must be guided by other symptoms than the temperature and blood count, particularly in influenza otitis. The indications for mastoid or sinus complications should be found in the otological manifestations and in the results of successive blood examinations, rather than in the course of the temperature.

Dr. Charles Hendee Smith, speaking of the cases that needed reincision, agreed with the otologists that one should not make two or three incisions within the first two or three days simply on account of a persistent fever. There were cases, however, in which the drums healed before the otitis had entirely cleared up. He had seen such cases which at the end of some days required reincision, and cleared up then.

Dr. Koplik stated that he examined the ears of every child who came to his office. One met with cases of otitis without temperature, some with absolutely no temperature above 100° F., and the babies were quite sick. There might be bulging of the drum, but sometimes pus was present with very little bulging, and the child had a temperature of 98½°, and in others a serous exudate. In some cases the ear did not bulge but was a little flat, and there was a distinct pus reflex. Why allow the baby to lie for twenty-four hours waiting for relief? If the drum was bulging he would not hesitate to incise it and incise it freely, although in a great many cases the exudate resolved if the drum was left alone. However, if pus was there, even if the drum was not bulging, if left to resolve the hearing might be impaired. He thought the otologists would recollect having seen cases in which a mastoid operation had been advised and rejected by the parent and reincision had cured them with a very good drum and the children were perfectly well afterward. There were cases that would get well with reincision and cases that would not. In order to distinguish between these two classes one must have large experience.

Dr. Francis J. Quinlan said he thought the time was ripe for a discussion of this kind which should have not so much the enthusiasm of youth as the wisdom of age. He had heard what Dr. Page had said with much satisfaction and a little suspicion. He had spoken of ear ache at night. In years gone by he had seen many cases of ear ache due to the recumbent position which favored obstruction of the Eustachian tube. The tubal membrane became congested and there was hyperemia of Schrapnell's membrane. That condition did not need incision. For all incision of the drum membrane was said to be a very simple procedure, it might cause luxation of the stirrup and dislocation of the incus; accidents of that kind had happened even in the hands of great experts. By applications one might expedite the depletion of the muscles of the Eustachian tube and the capillaries of Rosenmüller's fossa and re-establish the normal circulation of the ear. When the drum was pushed downward and forward and there was evidence of the presence of pus, it was timely to incise.

Dr. Sidney Valentine Haas said it took some courage to speak against early paracentesis, nevertheless he would like to relate his personal experience beginning fifteen years ago. It was taught at that time that unless the drum was incised early a mastoid operation would probably become necessary. In one family there were three cases of otitis media which were opened within the first twenty-four hours, and two of these had to have a mastoidectomy. That made him believe that if one waited for a short period it might be no worse. From that time he began to wait, increasing the intervals, and at the end of ten years he had no hesitation in waiting days. He was sure *early* paracentesis was not only not indicated but actually harmful. It was better to wait three, four, or five days than to make the incision during the first twenty-four hours. For the pain there was nothing that worked better than opium. Certainly the taking of an anesthetic was as bad as the short period of pain, which could be relieved by paregoric. Incidentally the primary pain when relieved only rarely recurred. He was speaking not only of congested ear drums, but of tender mastoids in patients with a high temperature. Dr. Haas recalled a case which Dr. Page and he had seen together. Dr. Page was called on the fourth or fifth day to do a myringotomy and had objected greatly to the delay. The infection in this case was a *Streptococcus mucosus*, and although the mastoids were involved they cleared up quickly. In the last four or five years he had not had a case of operative mastoiditis by following this policy of waiting. This did not mean that he would not have any cases of operative mastoiditis, but it did show that complications were not incurred by waiting. It was quite remarkable to see how these bulging and inflamed drums would subside without incision under hexamethylenamine and argyrol. Finally, one could judge by the appearance of the nasopharynx as to the progress of the process in the ear. The temperature dropped to normal long before the bulging subsided. The improvement in hearing was also a guide as to the conditions existing in the middle ear. There had been no case of impairment of function following his policy of waiting.

Dr. Seymour Oppenheimer expressed the opinion that they ought to be able to strike a sane attitude on this subject. In his judgment myringotomy was performed too frequently. He observed so often, in children admitted to his hospital service with some pulmonary infection or gastrointestinal disturbance, that almost uniformly the ear drums of these patients had been opened by the house staff or visiting staff. Most of these children had had reddened drums, but that did not indicate the necessity for myringotomy. The only indication was the evidence of an exudate in the middle ear space; indication might occur on the first, second, or even tenth day. The temperature did not enter into it, but it was the appearance of the drum membrane that was the guide. Exudates ofttimes formed very rapidly and at the time of examination myringotomy did not seem necessary, and then some hours later one was mortified to find that a perforation had occurred; that was something that could not be helped. As to the question of reincision, much depended upon the type of treatment employed after the original myringotomy, provided, of course, the myringotomy had been properly performed. Unfortunately, there was an impression that myringotomy consisted in nothing more than a stab. It should be an accurate surgical procedure and properly placed. In the after treatment it was most important to keep the incision patent and the middle ear freed of secretion, and for this purpose the employment of negative pressure by a simple suction apparatus was most satisfactory. If that type of treatment was employed the necessity for reincision of the drum would be much lessened. Dr. Oppenheimer disagreed with Dr. Haas' views. The question of the virulence of the particular infection in the individual case was all-important. The question of proper attention to the canal of the ear was of the greatest importance, and it was distressing to see men pay so little attention to asepsis and the surgical preparation of the ear canal and the ear prior to the incision. This brought up the question as to whether infection could be carried from without. Dr. Oppenheimer expressed the opinion that it could be so carried unless aseptic precautions were taken.

Dr. Page said there was as much difference of opinion on the subject of opening the ear drum among otologists themselves as there was between the otologists and the pediatricians, and as much difference of opinion among the pediatricians as among the otologists. There was equal support on both sides of the question from both groups of men.

Factors Determining That a Simple Mastoidectomy Is Indicated, in the Nonacute Stage of Middle Ear and Mastoid Infections.—Dr. Henry Koplik read this paper.

A Further Report on the Treatment of Persistent Otorrhea in Infants and Young Children by the Establishment of Postauricular Drainage.—Dr. Wendell C. Phillips presented this communication. He stated that eight years ago he had had occasion to outline the results of a series of studies regarding the more or less chronic purulent middle ear suppurations occurring during infancy and early childhood. Those studies were based on a large clinical experience, both in private practice and in his various hospital services. At that time he defined two distinct types of this particular affection as follows: (A) The persistent type, and (B) the recurring type. The persistent type applied to those cases in which an acute purulent inflammatory process invaded the middle ear spaces, and continued without abatement for an indeterminate period after the usual five to thirty days, which ordinarily might be considered as its normal course. This type of purulent otitis media should be clearly differentiated from the more common and recurrent type, in which recovery usually took place from each attack only to be followed by recurrence at varying intervals, or whenever the child became the victim of an acute nasal infection. In the recurrent type the children were almost invariably victims of diseased tonsils and adenoids, and their attacks usually ceased upon the removal of these offending tissues. The recurrent type, therefore, might be eliminated from this discussion, inasmuch as it hardly might be classified as non-acute in character unless, as a result of neglect to remove the diseased tonsils and adenoids, the otorrhea might finally become persistent and chronic in character. The persistent type of cases furnished a history somewhat as follows: During the course of an infection involving the upper air passages, or as a complication of certain chronic diseases, an acute ear suppuration appeared. Weakened by the primary general acute infection, the child's resistance became lowered and in many instances it was probable that some underlying dyscrasia, known or unknown, played its part. Earache followed, which might be relieved by a paracentesis, and from the onset the discharge was profuse, persistent, and of a character which plainly bespoke a severe type of infection. Mastoid tenderness was present and positive during the first few days, but might gradually disappear, unless the case was destined to become an acute mastoiditis requiring immediate operation. A large percentage of cases, however, showed a moderate diminution in the quantity of the discharge from the third to the seventh day, but it never entirely ceased. The temperature might gradually become normal, or nearly so, pain was not present thereafter as a prominent symptom, and there might be no marked drooping of the posterior-superior canal wall. The usual local measures of treatment consisting of paracentesis, cleansing, catharsis, and rest in bed, might have been carried out, but often clinic patients had received no treatment at all. In short, the case became one of chronic purulent otitis media, its significance being otorrhea, which continued without abatement. To the observer it became evident that the small tympanic cavity proper could not secrete the amount of pus which flowed from the ear, and that the mastoid antrum at least must be involved in the inflammatory process. Furthermore, it was evident that when such a discharge continued for a period beyond the end of the fourth week the element of chronicity had become established. It was also true that proportionately a large number of these persistent otorrheas occurred among the poor and ill-nourished applying for treatment in the hospitals and dispensaries. Of the underlying dyscrasias which served to prevent nature's efforts at repair, tuberculosis and syphilis were the most stubborn to deal with. Exami-

nations of the discharge and scrapings from a considerable number of this type of patients were examined for tuberculosis with positive results, even in cases in which no evidence of general tuberculosis existed. In this particular type of otorrhea even the removal of the tonsils and adenoids did not serve to terminate the aural discharge; neither did repeated paracentesis serve any purpose. The disease remained chronic, and unless relieved by surgical measures it progressed for long periods with serious impairment of hearing and often with fatal complications. It might be true that after long periods, even years, some of these cases did discharge spontaneously, but not until after extensive destruction had taken place with permanent impairment of the hearing. Regarding the treatment: All reasonable measures should be faithfully carried out for a reasonable period, which might be for a month to six weeks, this to include free drainage by paracentesis, a clean regime of local treatment, and attention to hygiene and general health. All these measures having failed, it was the writer's opinion that the quickest, safest and most rational measure to pursue was to establish postauricular, and hence through and through drainage by means of the simple mastoid operation. This was his conviction expressed eight years ago, and this opinion was based upon 20 or 25 operations. The lapse of years and the further study of cases, together with 100 operations performed by himself and his assistants, had in no way changed this conviction. In well-defined cases of chronic otorrhea of the type above described, he had never failed to find disease of the mastoid process, and had rarely failed to note the free escape of pus through the opening in the cortex at the time of operation. It must be remembered that these cases failed to exhibit almost all of the classical symptoms of mastoid involvement, except the discharge; yet upon operation all furnished evidences of extensive disease of the mastoid cells. Briefly stated, the reasons for advocating the simple mastoid operation in these cases were as follows: (1) It quickly terminated an otherwise persistent otorrhea. (2) It insured against an extension of local bone necrosis. (3) It relieved the patient of the dangers of possible serious and fatal complications, such as meningitis, brain abscess, and lateral sinus thrombosis. (4) Finally, the most important reason of all was the retention of the hearing function. It was scarcely necessary to add that this operation was not a dangerous one; neither was its slight seriousness to be compared with the dangers and discomforts attending a chronic aural discharge, and particularly the threatened deafness. It should be added that in the more chronic cases the simple mastoid operation had occasionally proven insufficient and a subsequent radical operation had become necessary.

Dr. Edward Lee Meierhof considered the question when an infection of the middle ear, accompanied by a flow of pus, became acute in an infant or young child. Was this to be determined by the absence of reactionary symptoms—principally fever and evidences of pain, either spontaneous or produced by pressure over the mastoid, or by traction upon the auricle, sometimes accompanied by restlessness during the sleeping period? If such were the case one would have to wait a very long time in many cases before the nonacute stage had arrived—or should one be governed by the element of time? The time element must be considered, because some cases would run their course and recover in from one to three weeks, even when untreated or badly treated. Also cases might recover after many weeks of purulent activity. Referring to mastoid involvement, Dr. Meierhof said that in his judgment every infection of the middle ear, especially in infancy and childhood, involved the mastoid antrum. Many knew of cases where there were distinct evidences of mastoid involvement which had recovered, operation having been advised but refused. In a child having a long-standing pyogenic infection of the middle ear, if the patient had no urgent symptoms and had not been properly treated according to one's judgment, then the child should be given the benefit of such treatment as had yielded successful results. If the patient showed no signs of improvement within a few days, no time should be lost in opening the mastoid, whether there were symptoms of mastoid involvement or not. The time had passed when the advisability of opening the mastoid was dependent upon vital indications. The preservation of hearing alone was sufficient ground for arresting the destructive pyogenic process, especially so when due to violent types of infection occurring in the course of scarlet fever, diphtheria, pneumonia, and other infectious diseases. Even a staphylococcus infection in a non-resistant individual could be as destructive as the more virulent types in others. In trained hands the danger from opening the mastoid was reduced almost to a minimum, but in spite of this one still had to encounter the fear and prejudice of an operation on the part of the family and, knowing this, one often postponed telling them what one's real judgment was. The factors that gave rise to an indication for a simple mastoidectomy in the nonacute stage of middle ear and mastoid infections were evidences of mastoid infection which were apparent. If the case was one of long standing without mastoid symptoms, but showed no signs of yielding to approved treatment—with or without the presence of symptoms other than discharge—operation was also advisable.

Relation of Diarrhea in Children to Otitis Media Purulenta.—Dr. Herman Schwarz read this paper, in which he asserted that over 90 per cent. of the cases usually classed as gastrointestinal, and associated with fever of one, two or three days' duration, had primarily nothing to do with the intestines. The intestinal symptoms were all secondary. One never met with a temperature due directly to the intestinal condition unless there was blood and mucous in the stools. If a child had an otitis media and diarrhea, mucus in the stools and vomiting the rise in temperature was not caused by the intestinal condition but by the otolaryngological condition. Hence in cases of this class the use of cathartics and high irrigations were useless, when the real cause of the trouble was in the ear. Another form of gastrointestinal disturbance was persistent vomiting. He had seen children with an elevation of temperature and vomiting for several days in whom a diagnosis of acidosis was made. These patients did not have diminished carbondioxide and the hydrogen ion concentration was normal. The condition was not an acidosis, but a parenteral condition secondary to otitis media or any other infection. The condition was no different when secondary to otitis than when secondary to other infections. In cases of marasmus it was well to bear in mind the possibility of an otitis media. The gastrointestinal disturbances associated with otitis media were probably not a real bacterial infection, but were more likely due to bacterial toxins or some unexplained form of toxemia. The first symptoms were loss in weight and restlessness, with perhaps a slight rise in temperature. If the physician did not look into the child's ears he would probably fail to recognize that the condition was a secondary and not a primary one. When the physician neglected to examine the ears, if the child was an infant he usually changed the formula. If the child was older nature usually took care of him. He did not wish to eat. However, it was not necessary to starve children with this type of gastrointestinal disturbance. They could take a fairly well balanced diet. In babies nature reduced the food by the vomiting and diarrhea and we could assist nature by reducing it still more. When the infection cleared up the ability to digest food returned, but in the infant at this stage one should go slowly and wait for the return of appetitie. In treating cases of parenteral infection malt soup was one of the foods that the child took well, and one could give it without fear of giving the child a real enteral infection, and in this way bring it gradually to take other foods.

Dr. Truman L. Saunders said that Dr. Schwarz had so completely discussed the subject that it simply remained for him to emphasize the fact that there was a distinct relationship between otitis media and disorders of the digestive system. This had been forcibly brought to their attention in the clinic. Children were brought to the clinic suffering from disturbances of the digestive apparatus and improvement in the gastrointestinal condition did not take place until the ear was opened. If this fact was recognized physicians might benefit many cases of gastrointestinal disease by making it a part of their routine to examine the ears of children.

Miscellany.

EXCERPTS FROM LITERATURE ILLUSTRATIVE OF THE POPULAR DISTRUST OF THE MEDICAL PROFESSION.

By EDWARD PODOLSKY,

BROOKLYN, NEW YORK.

If it is possible to perfect mankind, the means of doing so will be found in the medical sciences.—Descartes.

Medicine has been defined to be the art or science of amusing a sick man with frivolous speculation about his disorder, and of tempering ingeniously, till nature either kills or cures him.—Anon.

MEDICINE, of all human endeavors, is by far the most ancient and sacred, for it, above all, is dedicated to the ministrations of the human body, man's most concerned and sacred possession. This, perhaps, should serve to immune Medicine from anything undesirable, either in the form of active attack, or distrust expressed by words. But strangely, it has not, for almost from its inception, Medicine has been the target of all sorts of vilifications and abuses. What, then, should be accepted as the cause of the existence of this strange psychology?

Aside from the too prominent allegations that physicians, under pressure of economic conditions, resort too often to illegitimate uses of their profession, and that physicians often misuse their patients in search of scientific truths, the real cause of popular distrust lies with an inherent fault in Medicine itself. And more sad is the popular unwillingness to accept that fault as inevitable, at least for the present.

Medicine being that art that concerns itself more than anything else with the life and death of man, is expected to be the most perfect. Yet this is not true for many of the other human arts whose concern with human life and happiness is not as direct as that of Medicine are by far more perfect. Mankind, therefore, has placed in Medicine a wonderful belief that has continually been shattered. To the popular mind the least inefficiency in Medicine has assumed the proportions of a crime. Because of this shortcoming Mankind has come to regard Medicine as a sempiternally imperfect art, existing on a precarious right. But Mankind has not dared to do away with Medicine because of its supreme necessity, wherefore, that which had remained for it to do to show its distrust and disapproval of Medicine, has been by verbal thrusts at it, which are so abundantly found in the various literatures from the earliest times.

The Greeks' faith in Medicine was much the same as that of the peoples that came before them, and of those that came after them. There is a chill epigram from the Greek that runs: "Marcus, the physician, called yesterday on the marble Zeus; though marble, and though Zeus, his funeral is to-day." The Romans had among them many proverbs, born from unfortunate experience with Medicine, that showed their wariness of that ancient art. One Latin saying affirmed that there is "more danger from the physician than from the disease." Another said: "The surgeon buries his mistakes." The great Martial (Epigrams, Bk. 1, Ep. 47) declaimed:

"Diaule, the doctor, is a sexton made,
Though he is changed, he changeth not his trade."

In later times venomous expressions against the medical art seem to become more eloquent. In his "Le Médécin Malgré lui" (1666), Molière puts the following words into the mouth of his play physician, Sganarelle:

I think I had better stick to physic all my life. I find it is the best of trades; for whether we are right or wrong, we are paid equally well. We are never responsible for the better work, and we cut as we please in the stuff we work on. A shoemaker in making shoes can't spoil a scrap of leather without paying for it, but we can spoil a man without paying one farthing for the damage done. The blunders are not ours, and the fault is always that of the dead man. In short, the best part of the profession is, that there exists among the dead an honesty, a discretion that nothing can surpass; and never as yet has been known to complain of the doctor who killed him.

In another play "Le Malade Imaginaire" Molière ironically remarks through the lips of the soubrette Toinette:

This is pleasant! they are very impertinent to wish you, other gentlemen, to cure them! You do not attend them for that purpose; you are only there to receive your fees and to prescribe remedies; their affair to get well, if they can!

Molière did not confine his verbal thrusts at the medical profession to his plays and writings, but even in private life, at the least opportunity, was eager to air his views concerning the profession. He seems to have become quite famous for this, and one day when the king asked him how he got along with his physician, he replied: "Sire, we talk together; he prescribes remedies for me; I do not take them; and I get well."

Dumas was also deeply imbued with this spirit of medical distrust. It is said that one day he dined at the house of Dr. Gistel, a celebrity of Marseilles. After dinner the doctor brought his distinguished guest an autograph album, and asked him to add his name to it. "Certainly," said Dumas, and he wrote: "Since the famous Doctor Gistel began to practise here they have demolished the hospital—"

"Flattery!" cried the delighted doctor.

"And in its place made a cemetery," added the author.

Frederick the Great's distrust of Medicine remained with him to the end. When Dr. Zimmerman went from Hanover to attend him in his last illness the Emperor greeted him with the words: "You have, I presume, sir, helped many a man into the other world."

Several of the more well-known verbal launches found in poetry reflect, in a way, some of the mental characteristics of the authors. Quarles, in his "Hieroglyphics of the Life of Man," evidently felt peace in his soul when he said: "Physicians, of men, are the most happy; whatever good success soever they have, the world proclaimeth; and whatever faults they commit the earth covereth." Broome, in "Poverty and Poetry," felt his duty done when he wrote:

Though patients die, the doctor's paid,
Licens'd to kill, he gains a place
For what another mounts the gallows.

Dryden's accusation is found in the couplet:

The first physicians by debauch were made
Excess began, and sloth sustains the trade.

Addison, the brilliant essayist, wrote in the *Spectator*, a paragraph expressing his views of Medicine and physicians. The following is of special interest:

We may lay it down as a maxim that when a nation abounds in physicians it grows thin of people. . . . This body of men in our country may be described like the British army in Caesar's time. Some of them slay in chariots and some on foot. If the infantry do less execution than the charioteers it is because they cannot be carried so soon to all quarters of the town and dispatch so much business in so short a time.

In our own time attack on the profession still continues to come in forms of plays, novels, essays, and other forms of verbal expression. It will perhaps suffice to take George Bernard Shaw's drama, "The Doctor's Dilemma," as an example. The play is of extreme interest, and physicians should carefully note the points made, and of the truth in some of them, and fallaciousness in many of them. The preface to that jubilant satire itself is of great interest, and following excerpts are worthy of special attention:

It is not the fault of our doctors that the medical service of the community, as at present provided for, is a murderous absurdity. That any sane nation, having observed that you could provide for the supply of bread by giving the bakers a pecuniary interest in baking for you, should go on to give to a surgeon a pecuniary interest in cutting off your leg, is enough to make one despair of political humanity. But that is precisely what we have done. The more appalling the mutilation, the more the mutilator is paid. He who corrects the ingrowing toe-nail receives a few shillings; he who cuts your inside out receives hundreds of guineas, except when he does it to a poor person for practice.

Scandalized voices murmur that these operations are necessary. They may be. It may also be necessary to hang a man or pull down a house. But we take good care not to make the hangman and the housebreaker the judges of that. If we did, no man's neck would be safe and no man's house stable. But we do make the doctor the judge, and fine him anything from a sixpence to several hundred guineas if he decides in our favor. . . .

Again I hear the voices indignantly muttering old phrases about the high character of a noble profession and the honor and conscience of its members. I must reply that the medical profession has not a high character; it has an infamous character. I do not know a thoughtful and well-informed person who does not feel that the tragedy of illness at present is that it delivers you helplessly into the hands of a profession that you deeply mistrust, because it not only advocates and practises the most revolting cruelties in the pursuit of knowledge, and justifies them on grounds which would equally justify practising the same cruelties on yourself or your children . . . but when it has shocked the public, tries to reassure it with lies of breath-bereaving brazenness. That is the character the medical profession is got just now. It may be deserved or it may not; there it is at all events, and the doctors who have not realized this are living in a fool's paradise. As to the honor and conscience of doctors, they have as much as any other class of men, no more and no less. And what other men dare to pretend to be impartial where they have a strong pecuniary interest on one side. . . . To offer me a doctor as my judge, and then weigh his decision with a bribe of a large sum of money and a virtual guarantee that if he makes a mistake it can never be proved against him, is to go wildly beyond the ascertained strain which human nature will bear. It is simply unscientific to allege or believe that doctors do not under existing circumstances perform unnecessary operations and manufacture or prolong lucrative illnesses.

These accusations of Shaw's and of the other writers that were quoted before do not fundamentally express the reason for the popular distrust of Medicine. They have written simply what their prejudiced minds have sought to find and to magnify. The real cause of discontent with Medicine is its shortcoming in fulfilling a demand not yet possible.

511 Jerome Street.

The Two Hundredth Anniversary of the Plague at Marseilles.—This epidemic occurred so recently that much may be learned of it through documentary evidence. It raged during 1720-1 and took 50,000 of the 90,000 inhabitants of the city. Today, after 200 years, there are still occasionally found small foci of the bubonic plague. Nearly 2,000 years ago the Greek city of Massillia, forerunner of the present metropolis, was ravaged more than once by a pestilence which may have been the same. There was a visitation in 1586-7 and another in 1628-30, but the 1720-1 epidemic was by far the worst on record. Since there were many ambulant cases the number who escaped attack altogether must have been small. The disease was said to have been brought to the city by the vessel named *Le Grand Saint-Antoine*. This assertion was, however, disproved by the report of Professor Deidier of the University of Montpellier, who had been sent by the King to make an investigation, by reports of Drs. Robert and Rimbaud of the city, and by other testimony. This vessel sailed from Port Saïd to Tripoli and at the latter port probably took on infected subjects or merchandise This Tripoli was a town in Syria. The infected passengers who were booked for Cyprus were landed at that port, excepting one who died in transit. The sailors who threw overboard the cadaver soon came down with the disease. Other sailors and the ship's doctor were then attacked, and the Captain put in at Leghorn. Here the port surgeons pronounced the ship infected with plague. The ship proceeded to Marseilles, where the captain showed his papers and was promptly quarantined. He therefore escaped all responsibility for the Marseilles epidemic. Moreover his ship arrived after the outbreak of the disease, a number of prominent residents having already perished from it. Deaths continued to occur on the plague ship. The true mode of introduction was held to be—as so often happens—the work of smugglers, who cannot be reached by quarantine. Some dry goods were bought by a patron of smugglers and his 15 year old boy was the first known victim. He first came down with buboes and carbuncles. There was next a mass outbreak in the smugglers' quarters.

In commenting on the nature of the disease experts attributed it to the so-called pestilential germs of Kircher who predicated the existence of infinitely small living organisms. The aromatic vinegar recommended by the "city fathers" as a prophylactic was evidently of some value as a pulicide, for it enabled the thieves to rob right and left with impunity. Letters were disinfected by a special device and surgeons opened buboes with special long handled instruments, some of which are preserved in the local museum.—*Gazette des Hôpitaux*, xciv, 67.

SYPHILIS AND HIGH BLOOD PRESSURE.

BY BURTON PETER THOM, M.D.,

NEW YORK.

VISITING SYPHILOLOGIST TO THE HOSPITALS OF THE DEPARTMENT OF CORRECTION, BLACKWELLS ISLAND.

THE clinical aphorism that "a man is as old as his arteries," unlike most dogmatic epigrams, is true without exception. So constant is this fact that it may be raised to the dignity of a physiologic law that can be accepted without question. The relation, however, which many suppose to exist between arteriosclerosis or "hardening" of the arteries and high blood pressure, is not so intimate as to cause and effect as was formerly believed. We now know that a considerable degree of high blood pressure can exist for an appreciable length of time without causing any lasting thickening of the arterial walls. Also, we know that a considerable degree of thickening of the arterial walls can exist without a corresponding increase in the pressure of the blood flow. These conditions, however, I may say in passing are more or less anomalous and cannot continue for an extended period of time without ultimately giving rise to changes that are permanent. The study presented here, however, concerns arteriosclerosis as the probable cause of the examples given of high blood pressure, which I believe to be due to syphilis. From the evidence of the data collated and submitted herewith I am convinced that no other conclusion can be reached.

Before going further it will be well, perhaps, in order to arrive at a better understanding of the pathogenesis of arteriosclerosis, to discuss briefly the histologic anatomy of the arterial system as well as the biologic kinetics which control the pressure of the blood. In this last a number of new facts have come to the fore which have materially altered our former conceptions.

The arteries, except in their very smallest terminals, are made up of three coats or tunics, as they are called, the *tunica adventitia* or external coat, the *tunica media* or middle coat, and the *tunica intima* or inner coat. The outer coat is composed of connective tissue through which pass to the intima the blood vessels and nerves of nutrition and control. There are also a few fibrils of elastic tissue running through the substance of the outer coat, but the elastic tissue predominates in the middle coat, which, with smooth muscle fibers and a small amount of connective tissue comprise the elements of the middle coat. In the middle coat the elastic fibers are arranged in concentric layers which are held together by oblique fibrils of elastic tissue — the radial connecting fibrils of Dürck. The external layers of the elastic tissue of the middle coat are less condensed than the inner layers. The inner layers are fenestrated for the passage of the radial connecting fibers and the vasa vasorum. The internal coat is composed of a layer of flat endothelial cells. In early life this endothelial layer rests directly upon the middle or elastic layer, but as life advances this inner layer gradually loses its simplicity of detail and becomes more complex in that muscle and elastic fibers reinforce as it were the endothelial layer. In old age fibrous transformation of the muscle and elastic fibers of the two inner coats occurs which gives rise to the rigidity of the arterial tubes, which may be regarded as a natural retrogressive change concomitant with senility. However, when due to advanced years this thickening of the intimal coat is never as pronounced as the thickening of the medial and adventitial coats. For it is the undue and premature thickening of the intima which gives rise to the syndrome of high blood pressure.

The fibrous, and at times calcareous, transformation of the arterial walls due to the aging of the organism differs but slightly if at all from the sclerosis due to pathological causes. The sclerosis that is senile and the sclerosis that is pathological are both of slow development and it would not be outside the bounds of reason, in the light of knowledge now at hand, to say that they are essentially due to the same cause, that is, to irritation, continued over a longer period when senile and a shorter period when pathologic. This irritation is caused by substances in the blood stream which are undoubtedly various and at present not possible to define with anything like absolute certainty. Our increased knowledge of the physiology and pathology of the endocrine glands leads us to believe that these glands when perverted in their function are remote if not direct causes in many instances of arteriosclerosis and high blood pressure. In one disease, however—syphilis, and also in its congener yaws, the thickening of the arterial walls is due to an irritation that is peripheral and approaching from without — the *Treponema pallidum* is only rarely found in the blood stream even in the most active phase of the disease—the thickening of the intima which is characteristic of syphilitic arteriosclerosis is due to the irritation in part to the approach of the infecting organisms through the minute lymphatics supplying the vessels and contiguous to and continuous with them.

Ophuls is of the opinion that arteriosclerosis is due to a chronic intoxication, and the opinion of Barker is the same. Ophuls also states that "the

anatomic lesions seem to develop very slowly and progressively, even after the original infection is extinct." One of the facts that the more recent discoveries in the mechanism of high blood pressure have brought to light is that it is not dependent almost entirely, as was once supposed, on sclerotic contraction of the kidneys. As Barker in his very able monograph says: "it could not possibly be due to the increase of the arteriolar barrier in the kidney alone. It seems to be due rather to a narrowing of the lumina of the arterioles all over the body, to a general arteriolar constriction, partly of vasotonic origin, partly (at any rate in the later stages) of sclerotic origin." Barker further asks the question, "what causes this sclerosis, which begins as a functional narrowing due to the irritation already mentioned of the muscle and elastic fibers of the inner coats, the intima and the media. The question can be answered in so far as syphilis is concerned by assuming that as for the irritation in the blood stream which determines the initial hypertonus of the arterial walls, the biologic cause is to be found in the adrenals and the mechanical cause in the cellular infiltration and consequent transformation not only of these superadded elements but of the muscle and elastic fibers which are intrinsic to the inner and middle coats.

The researches of Oliver and Schäfer in 1894 led them to believe that the secretion of the adrenal glands sustained the tone of the vascular system. The later researches of Gley and Quinquaud are against this theory, but my opinion is that the conclusions of the earlier researchers are in the main correct. The explanation of the phenomena observed by Oliver and Schäfer is, I think, best given by Sajous that adrenalin in the blood stream enables the hemoglobin to take up oxygen in the pulmonary air cells, thus allowing it to be converted into oxyhemoglobin. The variations of the blood pressure are, in consequence of this, due to the presence of adrenalin in excess or deficiency as the increased or diminished oxygenation and metabolism acts on the walls of the arteries, causing a hyper- or hypotonus as the case may be. When this hypertonus is continued for a considerable length of time—when it becomes chronic as it were—the muscle and elastic fibers of the inner coats become fixed and set and the condition becomes permanent. With the increased tonicity the artery naturally becomes harder, and this hardness can often be appreciated by the sense of touch. This functional arteriosclerosis, as it is aptly designated by Pal, in time means an anatomically altered artery—an artery in which the walls have undergone degenerative changes as have been shown by Aschoff, Marchand, and Thoma. This contraction is seen throughout the entire vascular system as Volhard has shown.

The theory formerly held, and still held I may say by those who have not kept abreast with modern research, that increased blood pressure is primarily due to a sclerosis of the kidneys following some lesion of the same, is no longer tenable. For, as Kylin very cogently states, if a lesion of the kidneys is the original and underlying cause a symptomatic expression of a renal lesion must antedate the high blood pressure. Clinicians and pathologists both know that this does not always occur—in fact, it is rather infrequently noted. If injuries of the kidneys were the cause of high blood pressure it would necessarily follow that the greater the renal injury the greater would be the increase in the blood pressure. This we also know not to be. Mechanical factors can and do undoubtedly enter into the production of high blood pressure and arteriosclerosis, as the classic experiment of Ljungdahl with the pulmonary artery has shown; but mechanical factors cannot influence the entire vascular system except that they are inaugurated and kept at work as it were by factors which are strictly biologic.

That syphilis attacks the blood vessels has been known since the days of Severinus, but it was not until the time of Virchow that arterial lesions due to syphilis were systematically studied. What was formerly suspected or held as a hazy belief we now know, thanks to the researches of Gull and Sutton, Huebner, and many others since their day, to be a very common occurrence; in fact we know that the *Treponema pallidum* has a very decided predilection to lodge in the walls of the arteries and induce pathologic changes therein. The frequency of these changes and their early incidence is what I hope to prove in this thesis.

It has long been known that infection with the *Treponema pallidum* is local for only a very short time; that is, the disease becomes constitutional long before its first local manifestation—the chancre—appears. This has been proven conclusively by Metchnikoff and Roux in their experiments with prophylactic ointments, and later in the more carefully controlled and satisfying experiments of Brown and Pearce. These last two workers have shown beyond all question of a doubt how soon and how completely the infecting agents permeate the organism. Widespread and disseminated through every organ and tissue of the body almost from the beginning, syphilis undoubtedly quickly inaugurates the changes in the adrenals and the walls of the arteries which in time by slow accretion, as it were, leads to the generalized arteriosclerosis and high blood pressure which this condition connotes.

Syphilis attacks the three coats of the arteries—the adventitia, the media, and the intima. It also attacks and frequently obliterates the vasa vasorum—the vessels of the vessels which nourish all those sufficiently large to require a nutrient supply in excess of that supplied by the generalized nutrient body juices. The *Treponemata* advance by way of the vasa vasorum and the irritation they excite causes a proliferation—a purely defensive process by the way—of plasma cells and lymphoid cells and multinucleated giant cells. In not a few instances this cellular proliferation is more or less circumscribed and then projects either outward through the adventitia or inward through the intima into the caliber of the vessel. These circumscribed proliferations very frequently undergo central necrosis and in their architecture correspond to true gummata—for such they really are. Such neoplasms as these are found only in the larger vessels, and in those of smaller caliber these aggregations are not always so characteristic. Minute gummata frequently occur, however, and project into the lumen of the smaller arteries—especially is this so of the cerebral arteries. An interesting

and perhaps significant fact has recently been brought to light by Kolmer and Lucke in their study on the histologic changes produced experimentally in rabbits by mercurial compounds. In the changes occurring in the brain and meninges these workers observed: "These tissues showed an interesting and unexpected perivascular round-cell infiltration; curiously this change is regarded as more or less constant in syphilitic infection of these tissues, and our findings quite naturally raise the question of the significance of perivascular round-cell infiltration in the brain of syphilitic subjects who have taken mercury during life."

Instead of being circumscribed and thus partaking of the character of a neoplasm the cellular infiltration is frequently diffused throughout the media and intima and, as in all syphilitic inflammation, this cellular infiltration later undergoes fibrous transformation which naturally distorts and contracts the artery. In the smallest arteries, in which the outer coats are much more simplified than those of larger size, the intima bears the brunt of the attack and in consequence of the cellular proliferation of this inner coat the lumen of these small tubes is not infrequently entirely obliterated. This is obliterative endarteritis and is arteriosclerosis carried to its ultimate conclusion. It is this arteritis obliterans which is responsible for many of the phenomena of cerebral syphilis and also of the syndrome known as intermittent claudication.

It is well known to syphilologists and clinicians generally that hemiplegia occurring in patients under forty years of age is in the majority of instances of syphilitic origin. It is not perhaps so well known that the hemiplegia occurring late in life, after fifty years of age, is very frequently preceded by a remote syphilis. Vedsmand, in an analysis of eighty-one patients with hemiplegia which had occurred after the sixtieth year, obtained a history of previous syphilis in 15 per cent. He further quotes from a monograph of H. A. Thomas in which 740 cases of hemiplegia are recorded. He found the observations of Thomas in accord with his and concludes therefore that tardy hemiplegia in old syphilitics is more common than is usually supposed. I am in full accord with the findings of Vedsmand and Thomas. It is but added proof of the intimate relationship existing between syphilis as a causative factor in high blood pressure and arteriosclerosis.

As to the pathological changes in the adrenals due to syphilis, which I believe to be a most potent factor in the production of the high blood pressure so frequently encountered in that disease, I am unable to offer any definite data except that the *Treponema pallidum* has been found at autopsy in the gland and as long ago as the days of Virchow and Lancereaux pathological changes here were observed in those dying of visceral syphilis. Further confirmation as to the influence exerted by the gland in producing arteriosclerosis and high blood pressure is to be found in the condition known as *progeria* or premature senility which is invariably associated with atrophy of the gland. It is needless for me to call the reader's attention to the fact that senility and arteriosclerosis are synonymous and synchronous. Animals in which the adrenals have been extirpated die within forty-eight hours with symptoms of profound depression, low temperature, and low blood pressure. Stewart has shown that death in such animals was considerably postponed if pregnant or lactating, and he assumed that this might be due to the excess of cholesterin in their blood as this substance is increased in amount in pregnancy and lactation. He also observed that injection of cholesterin before and after operation for the removal of the glands prolonged the life of the animals. Recently, Henes has shown that the presence of cholesterin in the blood is an important factor in determining the presence or absence of the Wassermann reaction in any given serum. In this connection I need only mention the increased sensitiveness of the test when cholesterinized antigen is used. From what he has observed, Henes has—and rightly in my opinion—assumed that syphilis must cause an excess of this substance in the blood, which would further show that the disease must in some way act upon the adrenals. Glands with an anatomic structure like the adrenals offer an excellent nidas for the *Treponema pallidum*, and in the early and widespread dissemination of these organisms which occurs in syphilis there is no reason to doubt but that they are frequently affected to the extent of producing more or less permanent pathological changes which react upon the body metabolism by the consequent changes induced thereby in their secretions.

I shall now present the following protocol of the blood pressure measurements of fifty syphilitics from my service in the municipal prisons of the city of New York. Of these, twenty-five are women and twenty-five are men. The Wassermann reaction registered four plus in all of them. In none of them were there any noticeable cardiac or renal lesions as evidenced by stethoscopic examination or uranalysis. All of them were selected at random; no attempt being made to choose cases that would favor the contention herein expressed. It can be truly said that these patients represent an absolutely correct cross section of the syphilitic census of the two prisons and, I might add in passing, of the largest city in the world, the prisoners being drawn from all sections of the country and of all degrees of social status.

MALES.—J. C. age 33, white, single, infected eight years ago, ulcerated gumma of the right thigh; S. 140, D. 84, Average 56.

D. E. age 28, white, single, asymptomatic, date of infection unknown; S. 118, D. 68, Average 50.

P. B. age 35, white, single, infected ten years ago, gummatous ulceration three years ago for which he was treated with salvarsan and mercury; S. 134, D. 68, Average 66.

M. P. age 33, white, single, phagedenic chancre now present on the glans; S. 148, D. 82, Average 66.

G. G. age 38, white, single, chancre four years ago, no further symptoms and is now asymptomatic; S. 142, D. 78, Average 64.

G. B. age 32, white, single, infected eight years ago, tubercular syphilides now present on the face and arms; S. 140, D. 60, Average 80.

N. N. age 35, Chinese, single, chancre three years ago, for which he was treated with salvarsan and mercury, at present asymptomatic; S. 118, D. 68, Average 50.

P. D. age 19, white, single, infected one year ago, no secondaries, asymptomatic; S. 130, D. 74, Average 56.

H. H. age 22, colored, single, phagedenic chancre eight months ago, mucous patches in the mouth and on the scrotum, condylomata lata about the anus, scaling papules scattered over the body; S. 134, D. 80, Average 54.

C. L. age 31, colored, single, infected two years ago, no secondaries, at present asymptomatic; S. 130, D. 72, Average 58.

J. R. age 20, colored, single, infection denied, asymptomatic; no stigmata of congenital disease; S. 124, D. 72, Average 52.

L. R. age 32, white, single, chancre six years ago, asymptomatic since then; S. 154, D. 72, Average 82.

F. D. age 20, white, single, chancre eighteen months ago, no secondaries, complains of cephalalgia; S. 118, D. 68, Average 50.

C. H. M. age 28, white, single, date of infection unknown, asymptomatic, no stigmata of congenital disease; S. 124, D. 70, Average 54.

M. M. age 21, white, single, date of infection unknown, asymptomatic, no stigmata of congenital disease; S. 118, D. 68, Average 50.

J. S. age 28, white, married, infected three years ago, S. 140, D. 78, Average 62.

S. N. age 39, white, single, date of infection unknown, pupils unequal but react sluggishly to light and accommodation, patella and achilles reflexes absent; S. 148, D. 72, Average 76.

H. A. age 26, white, single, chancre three years ago, no subsequent symptoms, congenital stigmata present, undoubtedly a case of binary syphilis; S. 136, D. 74, Average 62.

N. W. age 28, white, single, chancre ten years ago, at present asymptomatic; S. 140, D. 80, Average 60.

A. I. age 31, white, single, chancre three years ago, light secondaries, at present asymptomatic; S. 140, D. 70, Average 70.

M. J. age 35, Chinese, single, chancre two years ago, at present asymptomatic; S. 120, D. 60, Average 60.

P. F. age 29, white, single, chancre nine months ago, no secondaries, at present asymptomatic; S. 138, D. 58, Average 80.

J. F. age 21, colored, single, chancre two months ago, papular eruption present; S. 128, D. 62, Average 66.

W. B. age 27, white, single, chancre ten years ago, gummatous ulcerations now present on the thighs; S. 132, D. 58, Average 74.

A. L. age 45, white, single, chancre ten years ago, at present asymptomatic; S. 148, D. 72, Average 76.

Before analyzing the blood pressure measurements herein given I desire to call the reader's attention to certan facts contained in this protocol which I believe are worthy of interest. It will be noted that of the twenty-five women only two, or 8 per cent., can recall the date of infection. This is in accord with the experience of most syphilologists and clinicians generally. The fact that in women the chancre is rarely indurated to the same extent as it is in men, and also owing to the anatomic conformation of the female genitals, is why, perhaps, the primary lesion of syphilis so often escapes their notice. It will also be noticed that all of these women are asymptomatic, at least in so far as gross cutaneous manifestations are concerned, and I might add further that in nearly every instance they were not aware that they were syphilitic until apprised of the result of the Wassermann test. This asymptomatic syphilis is also the form that is more generally encountered in women at present than it evidently was formerly. It also in a measure at least, helps to verify the belief held by many syphilologists—myself included—that syphilis is milder in women than it is in men. Whether this is due to increased phagocytosis in females as compared with males, as some believe, or because of increased iodine secretion owing to greater activity of the thyroid in females as compared to males, I shall not attempt to answer.

Of the twenty-five men, only five, or 20 per cent., were unable to recall the date of infection—the remainder all had a very distinct recollection of the appearance of the primary lesion. This is in marked contrast to the experience of the women in whom only two, or 8 per cent., could recall the appearance of the chancre. It will also be noted that of the men, six, or 24 per cent., showed tertiary lesions as compared to none shown by the women. This percentage of cutaneous tertiarism is approximately in accord with the statistics of Fournier

and others as to the occurrence of these lesions. It is also of interest to note that while none of the women showed any of the gross tertiary manifestations of the disease as compared with 24 per cent. of the men, none of the women had received previous treatment as compared to 80 per cent of the men. That there is a reason for these marked differences in the evolution of the disease in the two sexes I am convinced—a difference that many others besides myself have noted; future research directed along lines to discover this difference will, I believe, be rewarded with facts not hitherto suspected pertaining to the pathogenesis of the disease, especially as it affects the endocrines.

None of the women examined had reached an age when an increased pressure would be noticeable—the youngest being twenty-one years and the oldest thirty-nine years. However, if we consider a pressure of 110 systolic as normal for a woman of twenty years, it will be observed that thirteen, or 52 per cent., are above the normal; and if we consider a diastolic pressure not exceeding fifty as normal, the same number and percentage register above the normal. It will thus be seen that more than half of these asymptomatic syphilitic females showed an increased blood pressure.

Of the men examined the oldest was forty-five and the youngest nineteen. It will thus be seen that the age average of the two sexes shows very little difference. If we consider a pressure of 120 systolic as normal for a man of twenty years it will be observed that sixteen, or 64 per cent., are above the normal; and if we consider a diastolic pressure not exceeding sixty as normal, the same number and percentage register above the normal. It will thus be seen that high blood pressure is present in the men in an excess of 12 per cent. over the women. The number of women and the number of men showing an increased blood pressure total twenty-nine, or 58 per cent. Therefore it can be assumed that approximately one-half or more of all syphilitics irrespective of sex or lack of objective symptoms show an increased blood pressure. This pressure may not necessarily give rise to subjective symptoms; in fact none of the patients examined complained of any of the symptoms pertaining thereto. Yet, nevertheless, if we accept the axiom that the body ages with the arteries these patients are much further advanced on the path of life than they otherwise would be if they had not contracted the disease. Such being the case, they are also more vulnerable to attack from other life-destroying diseases. Although the eminent pathologist, Douglas Symmers, believes that syphilis is a disease of diminishing severity, and while in a measure I believe this to be true in so far as cutaneous lesions are concerned, yet I believe it to be more accurate to say that it is a disease of changing severity in that its tendency now is to attack the deeper structures which are even more vital than those on the superficies of the body.

The syphilitic factor in cardiovascular disease has not, in my opinion, been sufficiently recognized. Not excepting other chronic infections and toxemias, it is, I believe, the most frequent cause of the syndrome of high blood pressure and all that this condition ultimately connotes.

FAULTY ATTITUDES IN CHILDREN.

By JACOB GROSSMAN, M.D.,

NEW YORK.

CHIEF OF THE ORTHOPEDIC CLINIC, LEBANON HOSPITAL; CHIEF OF THE ORTHOPEDIC CLINIC, STUYVESANT POLYCLINIC; INSTRUCTOR OF ORTHOPEDIC SURGERY, NEW YORK POST-GRADUATE MEDICAL SCHOOL.

FAULTY attitude in children is one of the common conditions in which the old adage, "a little prevention is worth all the cure?" is readily applicable. Round shoulders or functional types of scoliosis when seen early can very easily be overcome. If permitted to persist structural changes occur in the bones, muscles, and ligaments, resulting in fixed deformities. Attempts to cure the latter type of cases have proven futile.

Incorrect posture is very rare in children who are enjoying good physical condition. The children affected usually lack general vigor and muscular development. It is in the latter class of children that especial precautions should be taken to prevent round shoulders, scoliosis, kyphosis and lordosis.

The vertebral column of the fetus generally forms one single curvature, the convexity of which is directed backward. During the first few months of its life after birth, the child retains this position. If the infant is retained in a recumbent position or on a firm bed a slight flattening of the kyphosis may occur. A soft mattress which yields to the weight of the infant will permit an increase in the kyphosis. An important change occurs in the vertebral column when a three or four month child begins to lift its head. The dorsolumbar region of the spine retains the original kyphosis, but the cervical region now changes from the kyphosis into the opposite, namely, a lordosis with the convexity forward. A second change in the shape of the spine occurs at the end of the first year when the child begins to stand on its feet and attempts to walk. The muscles of the back which hitherto have been used very little are now brought into action. These muscles arise from the sacrum and are inserted into the lower portion of the dorsal region of the spine. In contracting they force the kyphosis, which formerly was formed by the lumbar region of the spine, gradually forward and finally transform it into a lordosis. As a result of these changes the vertebral column which originally was a total kyphosis, now presents an anterior lordotic curvature in the cervicodorsal region, the original kyphosis in the dorsal region, and a lordosis in the lumbar region. Thus the fundamental S shape is attained.

A continuous and harmonious cooperation of numerous muscles is essential to retain the spine in its normal position. The posterior muscles located on both sides of the spine tend to increase the lordosis, while the anteriorly located muscles tend to augment the kyphosis. The normal posture is dependent not alone on the form of the spine, but is influenced also by the position of the pelvis. The connection of the pelvis with the spine by means of the sacroiliac articulation is rather rigid. For this reason the position of the spine is intimately associated with that of the pelvis.

The pelvic motions are based on an axis connecting both hips. In the recumbent position the pelvis is at rest, the thighs alone being able to perform

certain movements which are called flexion and extension. These movements result from the action of the flexor and extensor muscles of the hip. In the erect posture, with the legs fixed, pelvic movements are performed by similar muscular action. When the flexor muscles become active the anterior part of the pelvis is tilted downwards and the plane through the superior pelvic entrance becomes almost vertical. This pelvic position is called increased inclination of the pelvis. The reverse occurs when the extensor muscles of the hip are brought into action. The posterior part of the pelvis is then tilted downwards and the superior pelvic strait appears horizontal. This attitude is called decreased inclination of the pelvis. It is evident that the attitude of the pelvis exerts a marked influence on the carriage of the vertebral column as well as on the position of the trunk. In case of an inclined pelvis, i. e., when the superior pelvic strait is more vertical, the trunk would fall forward were it not for the action of the lumbar region of the spine, which owing to a marked lordosis, bends the spine backwards. Decreased inclination of the pelvis has the opposite effect. In this case the falling backward of the trunk is prevented by a marked kyphotic curvature of the lumbar region forcing the upper part of the spine forwards. In the normal posture, a line connecting the promontory and upper border of the symphysis forms an angle of fifty degrees with a horizontal plane.

To obtain prompt information as to the normal appearance of the spine and pelvis in a living subject, a vertical line should be drawn from the cervical region to the lowest point of the sacrum. Such a line in a normal individual must either touch the dorsal curvature or pass very near it. In addition to the shape of the spine and the inclination of the pelvis the other components which contribute to a normal attitude are of minor importance. Finally, in order to maintain a normal posture, it is necessary to hold the shoulders backward in a position midway between high and low elevation.

Kyphosis—The formation of kyphosis of the spine is explained by the assumption of an habitual attitude characterized by an increased posterior curvature of the spine. It may involve the entire spine from the first cervical vertebra to the sacrum. Such curvature of the spine is called total kyphosis. It occurs very rarely and is usually congenital. It is probably the result of deficient amniotic fluid in intrauterine life where the kyphotic position was retained for a long period, finally becoming rigid in this attitude. The deformities of the spine which present pathological kyphosis in the dorsolumbar region are more frequent, while the cervical part presents the physiological lordosis. This form of kyphosis is most frequently observed during the first and second year in rachitic children.

Rachitic Kyphosis—A characteristic symptom of this form of round back is the marked posterior projection of the lumbar portion of the spine. Assuming the sitting posture in bed at too early a period is the main cause for this marked kyphosis. Extension of the legs at the knee joint and the rectangular flexion in the hip force the muscles to contract and to rotate the pelvis backward in such a way as to decrease the inclination of the sacrum and to alter the forward position into a more posterior direction. The lumbar region following the excursion of the sacrum necessarily forms an increased kyphosis. Carrying children on the arm aggravates the disposition to kyphosis. Finally, faulty arrangement of the bed, too many pillows and a soft mattress instead of a hard even one may result in an increased kyphosis of the soft rachitic vertebral column. Rachitic kyphosis becomes especially damaging when children fail to stand and walk at the proper time. At that time the factor is suppressed, which, as described above, has the greatest influence on the development of the physiological lumbar lordosis. This results in rigidity of the lumbar region of the spine in the form of an habitual kyphotic curvature. Very little attention is given to rachitic kyphosis. Although the marked degree of kyphosis which is found in children during the first and second years disappears later to a great extent, still much trouble has often resulted from kyphoses of rachitic origin. These children occasionally develop scoliosis or round shoulders in their second decade.

Diagnosis—Inclination to kyphotic posture is best observed in infants while in the sitting position. The spinal column of a normal child of six months when seated with the hip and knee joints in rectangular flexion, assumes the following position: lordosis in the cervical region, kyphosis in the dorsal region and slight lordosis in the lumbar region. Any marked posterior projection of the lumbar portion of the spine must be looked upon as an inclination to kyphosis. An incipient rigidity can be more readily detected when the child lies upon its abdomen. Upon grasping the child by the legs and raising it a trifle the spinal column if normal assumes the most marked lordotic shape possible. The rigid rechitic kyphosis, however, presents a posterior convex curvature in the dorsolumbar region of the spine.

Treatment—In the first place, treatment should aim at remedying the general rachitic affection. Rachitic children should sleep upon an even hard mattress, should not be carried on one arm, and should be prohibited from sitting in their carriages with the knees extended. Where kyphosis is developing a pillow or cushion should be placed over the lumbar region of the spine so as to induce a lordosis. When this is of no avail a Bradford frame or a plaster bed can be utilized with excellent results.

Round Shoulders—In older children, especially during the school period, a type of kyphosis makes its appearance which, although embracing the dorsal and lumbar portions of the spine as in rachitic kyphosis, exhibits the most marked projections a little higher up, usually in the center of the dorsal portion of the spine and not in the lumbar portion. This condition is also known as stoop or slant shoulders, round back, round hollow back and bowed back. Most children whose bad carriage elicits steady complaints from parents exhibit this postural anomaly. The causes of this deformity may mainly be traced back to the fact that children hold and fix their trunks with as little muscular action as possible. To hold the spine in such a position as to conform with the physiological

curvature, a continuous action of the erectores spinæ as well as the flexor and extensor muscles of the hip, is essential. However, the children seek to fix the spine by positive contraction of muscles and checking of ligaments. This is done by the dorsal and lumbar portions of the spine assuming a totally kyphotic curvature. The ligaments inserted along the posterior aspect of the spine, the ribs and the spinal processes, act in opposition, while the vertebral bodies are pressed together at the front of the spine, thus producing a rigidity of the otherwise flexible structure.

Aside from these vertebral changes, other variations of normal posture are often found in these cases and may be briefly mentioned. In almost all dorsolumbar kyphoses, a markedly decreased inclination of the pelvis is noticeable. This attitude, as in kyphotic fixation of the spine, is likewise caused by passive contraction of ligaments, which act as a substitute for the tiring muscles.

Children with weak or inactive muscles and round backs avoid all straining motions of the flexor and extensor muscles of the hip, which are required in maintaining the normal posture of the pelvis. Instead they persist in lowering the posterior part of the pelvis until the muscles of the hip which are inserted along the anterior border of the pelvis (tenso fasciæ femoris, sartorious and iliopsoas) become quite tense as well as the anterior ligaments of the capsule of the hip joint. Finally, these children with round backs allow their shoulders to drop forward and downward in order to eliminate as much as possible the irksome activity of the shoulder muscles. In general the attitude is familiar, the head is carried forward and somewhat flexed, the physiological curve in the dorsal region is increased and the dorsal region is prominent behind, in which backward curve the lumbar region may share, or there may also be an increased lumbar curve forward. The shoulders droop and the chest is narrow and flat, while the scapulæ are prominent on their posterior borders and the inferior angles may project markedly, forming the so-called winged scapulæ. Weak feet are frequently present. As a rule the general vigor and muscular development are below the average in children who have round shoulders. They are clumsy in their movements and walk heavily. In some cases the deformity can be corrected by the patient or by gentle pressure with the hands, but in most of the cases the deformity cannot be wholly corrected by gentle passive force, as the persistent maintenance of malposition has led to adaptive shortening of the soft parts concerned.

The affection is not wholly one of the spine, but implies a disturbance of relations from the feet upwards, because an increase in the backward curve of the spine implies a forward curve or forward displacement somewhere else to balance it. Hence round shoulders is not to be considered as an affair wholly concerning the dorsal spine or shoulders.

Etiology—In general the causes of round shoulders are: (a) Conditions producing muscular weakness. Chief among these conditions are rapid growth, overwork and impure air at school, improper school furniture, acute illness and bad hygiene at home. (b) Conditions producing a flexed position of the spine for prolonged periods. School furniture which fails to support the back, errors in vision which necessitate stooping over the books in reading, careless attitudes of reading and sitting permitted at home, are chief among these conditions. The child with normal eyes should not have to hold the book nearer than twelve to fourteen inches. (c) Overweighting of the shoulders by improperly arranged clothing. The customary method of supporting a child's clothes consist in the use of a waist, loose around the abdomen, to which drawers, skirts or trousers are buttoned. To this waist are also attached side elastic stocking supporters, which are kept tight to prevent the stockings from wrinkling. This waist is supported above by two shoulder straps passing over the shoulders near their tips. The entire weight of the clothes and the added pull of the stout elastics is thus transferred to the child's movable shoulders, of all the parts of the body the least suited to hold against a steady downward pull. This pull is transferred to the spine by the muscles clavicles, and thorax tending to produce flexion. The remedy of this condition consists in supporting as much as possible the clothing from a belt, using round garters, or in cases with markedly prominent abdomen the use of a corset waist. (d) Rickets is one of the important causes of faulty attitudes in children.

Pathology—The pathological changes in round backs of school children consist principally in an overextension of the ligaments and muscles situated on the posterior aspect. In case of a persistent kyphotic posture the soft parts become shortened in front and the intercartilaginous surfaces, as well as the osseous vertebræ undergo changes to the extent that the posterior parts grow thicker and the anterior parts become thinner, resulting finally in a decreased flexibility of the spine and producing a rigidity.

Prognosis—The attitude of round shoulders is not to be regarded as on which will be outgrown. It requires treatment and with proper attention and hygiene the prognosis for recovery in young children is good. In older children and adolescents improvement and perhaps cure are to be obtained. Even in young adults an improved position of the shoulders and a better expansion of the chest are to be secured with adequate treatment. If the attitude of round shoulders is permitted to persist into adult life there are certain respects in which it may affect unfavorably the health of the individual. The flat chest and diminished chest expansion mean impaired respiratory capacity and diminished room for the heart and the large abdomen favors ptosis of the abdominal viscera. Moreover, the bowed spine is generally a weak spine and such patients are liable to static backache.

Treatment—The treatment of this condition resolves itself into one of exercises which aim to methodically strengthen the muscles of the shoulders, back and pelvis. The following simple exercises have proven helpful. (1) The patient assumes an erect position with the hands clasped together at the back. The body is bent forward, then the arms are projected backwards with extended elbows and the shoulders are drawn together. Finally, with the shoulders and arms held in the above position, the trunk is gradually straightened, forcing the spine into a lordotic curve. (2) The

patient stands erect holding the clasped hands behind the head, elbows flexed, during a forced expiration the arms are brought forward until they are parallel to each other. Then while the arms are carried as far backward as possible, a deep inspiration is taken and at the same time the patient raises its body by standing on its toes. (3) Walking in the fresh air is very beneficial. Where there is rigidity, hanging from rings or reclining over a cross bar may be tried. These active and passive exercises must be persisted in for one half to one hour daily. In children with round shoulders especial attention should be given to the construction of seats. If the seat is without a back children will surely assume a kyphotic posture. Finally, the employment of braces and corsets to straighten the body must be discussed. As a rule it is best to discourage the use of appliances of any kind, because as long as they are used they exclude muscular activity and therefore tend to weaken them.

Lordosis—Lordosis may be either primary or secondary. Primary lordosis, though it occurs, is fairly rare. The writer has seen only one case of primary lordosis in a fairly large series of static deformities in children. This case was a boy about seven years of age. He recovered completely with two years of exercises and a support. It is usually the result of muscular weakness. Lordosis, secondary to other conditions, occurs more commonly. It is usually secondary to hip disease. In marked flexor contraction in one hip joint occurring after coxitis the patient in order to place the diseased side parallel to the normal one, is forced to rotate the pelvis in such a manner as to considerably tilt the anterior half downward. With this maneuver the sacrum assumes a more or less horizontal position. The lumbar portion of the spine follows this motion. To prevent the trunk from falling forward the upper half of the spine must be bent backward, while the lumbar portion assumes a marked lordotic form. Lordosis in bilateral dislocation of the hip results from the location of the heads and shafts of the femora behind the sockets. The front part of the pelvis becomes too heavy, sinks downward and forces the patient, for the sake of retaining his balance, to compensate with an extreme lordosis of the spine. Finally, an excessive lordosis has also been observed in cases of spondylitis.

Scoliosis is a lateral deviation of the spine, accompanied by rotation of the vertebræ upon their vertical axes. It is possible to have a lateral deviation of the spine without rotation of the vertebræ, these cases being strictly those of the functional lateral curvature rather than of true scoliosis. It is true that many cases of scoliosis begin as a functional lateral curvature and the rotation of the vertebræ occurs at a later period; this is especially so when the spinal muscles are weak. Simple functional lateral curvature if treated early does not necessarily give rise to true scoliosis.

Etiology—Experiments have proven that the most essential factor in the production of scoliosis is the transmission of the weight of the upper part of the body through a vertebral column, which, by the enfeeblement of its various muscles, or by the habitual maintenance of a faulty position, has undergone lateral deviation. The constant pressure acting upon a spine so deflected will inevitably produce rotation of the vertebræ on account of the conformation of the constituent parts of the curved spine and their articulations. The condition is predisposed to by any cause of general debility, particularly rickets and anemia, and is greatly favored by overfatigue and the constant assumption of faulty postures. The latter, by causing a deviation of the spinal column, place the spinal muscles on one side at a mechanical disadvantage compared with those on the opposite side and if a faulty position be assumed habitually, the muscles that are at a mechanical advantage will maintain or even accentuate the curvature, eventually producing the rotation of the vertebræ. This rotation always occurs in one direction, the bodies of the vertebræ are rotated outward toward the convexity of the curve, while the spinous processes are rotated inwards toward the concavity, i. e., toward the middle line of the body.

There are a group of cases in which the curvature is the result of inequality in the length of the supports of the spine. This group is of extreme importance and embraces many causes which are constantly met with. Unless the base of support of the spine (sacrum) be horizontal, a certain amount of curvature must necessarily result. However slight the obliquity may be, it is sufficient to prove the starting point of a severe scoliosis in susceptible individuals. In robust persons, on the other hand, this obliquity may be corrected easily and pass practically unnoticed. A very common cause is obliquity of the pelvis the result of inequality of the length of the two lower limbs. This may occur from various causes, such as tuberculous hip disease, congenital dislocation of the hip, the arrest of development which follows infantile paralysis and simple asymmetry. In weak individuals scoliosis is a common complication of severe genu valgum or even of weak feet. The primary curve in this group is usually in the lumbar or lower dorsal region.

Another group of cases results from an inequality in the weight borne on the two sides of the spine. Common examples of this are seen in nursemaids who habitually carry children upon one arm, laborers carrying hods, pails or heavy weights always on the same side. As long as the individual is strong and vigorous and the weights carried are not out of proportion to the strength of the muscles, the latter are able to maintain their tone and retain the spine in the erect posture. When, however the muscular system is weak or the weight is excessive and especially when it is carried for long periods at a time, scoliosis is apt to result.

Weakness of the spinal muscles, aided by the habitual assumption of a faulty attitude is responsible for a large number of cases of scoliosis. As long as the patient is in good health the muscles upon the two sides of the spine act together to maintain the spine erect; but in certain individuals and especially at certain periods of life, muscular weakness occurs and the muscles are no longer capable of maintaining the spine in its normal position for any length of time. This is most frequently seen in girls between the ages of twelve and seventeen, a period which comprises the onset of menstruation and the abandonment of the free

vigorous life and exercises of childhood. It is a period often marked by a predilection for sedentary habits, the semi-recumbent position, confinement to heated rooms and the keeping of late hours, together with the assumption of tight fitting clothes which hinder the free play of the muscles so essential to the proper development of the trunk. The condition is still further aggravated if anemia is present.

One of the most potent factors in the production of scoliosis is overfatigue, due to prolonged standing, sitting or walking. Nursemaids, typists, school children continuously engaged in reading, writing or piano playing may develop scoliosis, should the general health be such as to cause enfeeblement of the muscles. A similar result occurs in girls who are in the habit of riding horse back for periods long enough to produce fatigue to the muscles of the back, leading to a faulty position of the spine. Scoliosis may also be produced in children if they are always carried on the same arm.

Scoliosis may be secondary to other affections of the spine or thorax. In these instances the curvature of the spine is mechanical and is produced by some alteration in that structure itself or in the capacity of the thorax. Familiar examples are lateral curvature secondary to empyema, collapse of the lung, rickets and tuberculous disease of the spine. Congenital defects such as supernumerary or absent ribs, variations in the size of the processes of the vertebræ, defects in the bodies of the vertebræ may all play an important role in the production of scoliosis. Paralysis of the back muscles resulting from infantile paralysis often gives rise to a very resistent type of lateral curvature.

Pathology—After a time organic changes occur in the ligaments and the bones so that a curvature, which at first could be easily rectified by appropriate position, becomes more and more permanent. The first change that occurs is an alteration in the various fibrous structures on the two sides, those upon the convexity being stretched and those upon the opposite side being proportionately shortened. In advanced cases, the vertebral bodies themselves become altered so that each is somewhat wedge shaped, the base of the wedge being directed toward the convexity of the curve. The surfaces of the various articular processes also become altered in direction. These bony changes are permanent and account for the intractability of the severe cases.

Symptomatology—Sometimes the spine is bent to one side in a single large C shaped curve, which may either involve the entire vertebral column, or may be confined to the lumbar or dorsal regions. Should a curvature of this type be marked, it will be necessary for one or more compensatory curves to be formed in the opposite direction for the adjustment of the center of gravity of the body as otherwise the erect position could not be maintained. These compensatory curves have their curvature in the opposite direction to the main one and are smaller in extent than the primary curve. In the common form of scoliosis there are generally two curves which have their convexities in opposite directions, so that the spine somewhat resembles the letter S. Of these, one is usually called the primary and the other the secondary curve. The primary curve cannot always be clearly distinguished, but a fair idea can generally be gained by considering the mechanism of the formation of the curvature. If due to an inequality in length of the lower extremities, the primary curve will be in the lumbar or lower dorsal region, whilst that in the upper dorsal is merely compensatory; on the other hand, if the curvature is due to faulty position, the primary curve is usually in the upper dorsal region, whilst the compensatory curve is below it. When the primary curve is very marked there may be three or even more curves in the spine; the primary curve is then generally very acute and at both ends of it there is a compensatory curve. This is usually the case in severe dorsal curvature, when there is a compensatory curve in the cervical region and another in the lumbar region.

A marked objective symptom is asymmetry of the thorax. The shoulder on the side of the convexity of the curve is higher than the other; the intercostal spaces are considerably wider on that side, whilst they are narrowed upon the side of the concavity. The spinous processes deviate from the middle line. The distance between the lower ribs and the crest of the ilium on one side is much increased, whilst there is a deep fold in the corresponding situation on the opposite side. The total body height is diminished. When there is much rotation of the bodies of the vertebræ, the thorax undergoes extensive deformity; the ribs on the side of the convexity of the curve are carried backwards, whilst they are carried forward on the opposite side. The shape of the two sides of the thorax is therefore greatly altered. On the side of the convexity the vertical measurement of the thoracic cavity is increased, owing to the separation of the ribs, but the transverse one is lessened. On the side of the concavity the reverse is the case, but probably the cubic capacity on the two sides is but slightly altered. The angles of the ribs on the side of the convexity become more acute, whilst those on the opposite side either remain unaltered or become very obtuse. The result is a prominent ridge upon the side of the convexity formed by the angles of the ribs with the erector muscles over them. The arm on the opposite side hangs away from the thorax.

The subjective symptoms are usually slight, but may become exaggerated in neurotic individuals or in those in whom the deformity is extreme. There is aching pain and a feeling of weariness in the back and loins, sometimes extending down to the thighs. When the deformity has been present a long time and extensive bony changes have occurred, there may be considerable pain partly from the pull upon the stretched ligaments and partly from direct pressure upon the nerves or viscera. The lung may be compressed upon the side of the convexity and patients with long standing curvature are apt to suffer from severe bronchitis; the heart may be displaced and the liver and spleen pressed upon.

Examination—The patient should be stripped to the hips and should stand in a position of ease with her back to the examiner, the garments being fastened with a safety pin to prevent them slipping down and to avoid the constant changes of position that accompany the endeavors to hold them up. The spinous processes should then be marked

upon the skin with a carbon pencil and a sheet of paper pressed over them so as to obtain a permanent record; the marks made by the pencil will be transferred to the paper, which can be varnished and retained for reference. A slight deviation of the spine is best detected by letting a plumb line fall from the spinous process of the seventh cervical vertebra. Any deviation of the spinous processes from the vertical can be measured. The next important point is to ascertain whether there is any obliquity of the pelvis. The patient is turned around, and the examiner, standing or kneeling in front, places a thumb upon each anterior superior spine and notes whether they are on the same horizontal level; in case of doubt, the patient should stand erect, with the feet together and the length of the lower extremities should be measured from the anterior superior spines to the floor on each side. The presence of flat-feet or knock-knee should also be looked for. The next point is to determine what amount of alteration can be made in the curvature by alteration in position; in other words, the flexibility of the spinal column is tested. The patient should be directed to hold herself as erect as possible, and any alteration in the curvature of the spine is then compared with the measurements taken in the position of rest. In slight curvatures marked improvement is produced by the effort of standing to attention. Should the curvature be due to the inequality in the length of the lower extremities, suitable blocks must be placed beneath the shortened limb so as to make the pelvis horizontal and the effect upon the curvature noted. In early cases this will obliterate it entirely. The patient should next be made to stand erect and then bend forward gradually until the fingers touch the toes. The amount of rotation can then be estimated by noticing the asymmetry of the ribs. If it be desired to record this, a tracing of the contour of the posterior aspect of the ribs can be made with a pleximeter.

Prognosis—The method of examination is of great importance in its bearing on the prognosis and on the treatment, as it demonstrates the amount of flexibility remaining in the spine and gives a good indication of the best result that can be expected from treatment. When suspension fails to obliterate the curve entirely, we may fairly conclude that ligamentous and even bony changes have occurred in the spinal column and that therefore perfect restoration of the erect position is not likely to result from treatment. On the other hand, a hopeful prognosis may be given in those cases in which the spine straightens out completely and the chances are that with proper care and suitable treatment the curve can be entirely obliterated. A number of cases, especially those that are the result of some defect in the general health, will undergo spontaneous cure as soon as the muscles regain their tone. Of these, the ones which are more prone to undergo spontaneous cure are those in which there are two slight equal curves rather than a large single C shaped one, which tends to increase and to result in important rotation changes since there is no compensation. When the curvature is due to inequality in length of the two lower extremities the cases are very amenable to treatment if seen within a reasonable time and a good result can generally be obtained. The opposite is the case when the curvature is the sequela of some chest disease, such for instance, as empyema. The most important feature in the prognosis is the condition of the patient's health. Scoliosis associated with profound anemia is most difficult to treat and little beneficial effect upon the curvature can be expected unless the anemia can be successfully treated. The most difficult cases of all are in anemic girls about the age of puberty who also suffer from dysmenorrhea; when these condition are combined with a neurotic taint, the case may prove intractable. The age of the patient at the onset of the curvature is of great importance. In a very young child the vertebræ are soft and easily molded and there is a long period during which the spine may undergo serious structural alterations unless it be maintained in proper position. When the disease begins only a short time before ossification is complete, however, there is little time for great changes to occur in the vertebræ. The curvature will therefore develop much more slowly.

Prophylactic Treatment — Any patient with inequality in the length of the lower extremities should receive treatment directed to remedying the resulting obliquity of the pelvis. When a patient has been the subject of hip disease and is left with a deformity and shortening of the limb, the deformity should be remedied as far as possible and a high shoe should be worn on the affected limb, to make the two limbs the same length. Congenital dislocation of the hip should receive appropriate treatment. Apparatus will be required for cases of arrest of development following infantile paralysis, whilst genu valgum and flat-feet should receive proper attention. When heavy weights are carried upon one side, emphasis should be laid upon the importance of alternating the side upon which to carry them. Nurse maids should be told to carry children alternately upon either arm. When an arm has been lost, the patient should be forbidden to carry heavy weights; if enough of the limb remains to permit the fitting of an artificial limb, the weight should be carried alternately by the natural and artificial limb. When there is weakness of the spinal muscles, the ordinary rules for personal hygiene must be insisted upon. Weakly children or those suffering from rickets should be carried in the horizontal position; they should never be carried upright even when they have become strong unless they can be carried alternately on either arm. Massage of the back muscles with application of sea water douches is helpful. Special care is required in the case of the rapidly growing girls who are approaching the period of puberty. All heavy or constricting clothing about the chest and abdomen which interfere with the free play of the thoracic, abdominal, and spinal muscles should be forbidden. The child should be encouraged to play games, to lead a healthful outdoor life and to go through a mild gymnastic course. Sedentary habits, the desire to remain in the house in the recumbent position reading novels should be discouraged. The life of the two sexes should be assimilated as much as possible. Corsets of any kind are detrimental and if employed should not be permitted to compress the chest. This is about the period of life at which curvature is apt to occur as the result of faulty position. Some atten-

tion has been directed to the possibility of producing lateral curvature by faulty positions during sleep. Many children sleep upon the back. This is obviously the best position. A large number, however, lie on one side. If a child is in the habit of lying more upon one side than on the other, lateral curvature may occur. It is well therefore to encourage sleeping upon alternate sides if the child is unable to sleep on its back. The mattress should be firm and a feather bed should be avoided. The positions usually adopted by children at school when sitting at a desk, writing, drawing or when playing the piano are often faulty and may produce scoliosis. The child is generally either seated upon a form without a back or upon a chair the back of which is too straight and not high enough, while the seat is too far from the ground and there is a lack of proportion between the height of the desk and the chair or form upon which the child sits. The result is that the child soon becomes tired, brings the pelvis to the edge of the chair in order to enable the feet to touch the ground and support him and he is often obliged to tilt the pelvis in order to bring one foot into contact with the floor. The spine is thus unsupported and the child either stoops forward or bends to one side so that he may rest the elbow upon the desk at which he is writing. The lack of proper proportion between the height of the seat and the desk plays a very important part, for, when the desk is too high, the right arm has to be elevated if the child wishes to write, while if the desk is too low, it has to be depressed and the left shoulder is consequently raised. This may lead to a marked lateral curvature in a weakly child. The chief requisites for a school seat and desk are as follows: The back of the chair should extend upward as high as the shoulders and should be prolonged high enough to support the head, if the child suffers from a weak spine. The seat should be at such a height from the ground that the feet rest easily upon the floor, or upon a foot-rest inclined at an angle of about twenty degrees. The breadth of the chair seats should be equal to the length of the children's thighs and there should be just room between the seat of the chair and the under surface of the desk for the thighs. The precise measurements usually recommended are that the lower edge of the desk should be an eighth of the height of the girl and one seventh that of a boy above the seat of the chair. The writing desk should have a gentle slope so that the child will not be forced to bend forward too much when he wishes to read and write.

Any defect of vision should receive proper attention. Exercises to develop the chest muscles should be prescribed unless the child be obviously robust. Massage will also be called for when there is any actual weakness of the spine muscles; this important factor in treatment should never be omitted. When there has been disease in the chest, little can be accomplished in the way of prophylaxis. In cases of Pott's disease and rickets appropriate treatment for the disease will stave off the onset of scoliosis. After empyema or collapse of the lung, some curvature is inevitable; it may, however, be minimized by prescribing exercises directed to bending the spine in a direction opposite to that in which the curvature is expected to occur. These exercises should be begun before any curvature has been detected and should be persevered with for many years.

Active Treatment—In the scoliosis of infancy, the treatment recommended in kyphosis also applies. The general health requires attention; rickets must be treated by proper feeding, medication and hygiene. The child should be retained in a horizontal position, either in the arms or upon a suitably padded tray or basket. After the first year, the back support recommended for kyphosis may be employed, but recumbency must still be insisted upon, so that the back may be relieved from superincumbent weight. The child should always be sent to the country or the seashore for a considerable period if possible and massage to the back muscles should be applied night and morning. Walking should be discouraged. Mothers are anxious that the children begin to walk early, but the importance of the recumbent position should be pointed out and attempts at walking prohibited. The child should be encouraged to sleep upon the back, and may if necessary be fastened down upon a suitably padded wicker tray in that position. Should there be a marked curvature, however, the lateral position may be substituted for the dorsal, the child being taught to lie upon the side of the convexity of the curve in the dorsal region, with a firm pillow interposed between the mattress and the thorax, the object being to unfold the curve. The mattress should be firm; a feather bed should be avoided and the child should sleep with the head supported by one pillow.

SCOLIOSIS OF CHILDHOOD—Great care must be exercised in the treatment of curvatures during this period of life, for, although on the one hand the spine is extremely flexible and therefore can be easily influenced by this treatment, this fact may be an actual source of danger, because the curve, if neglected, will lead to such marked distortion of the bones when they become fully ossified as to render the treatment difficult. Before proceeding to attack the curvature itself, any cause that may originate or maintain the vicious position should be eliminated. Any obliquity of the pelvis, due to inequality in the length of the lower extremities must be remedied by suitable means, such as shoes or operation. Any faulty attitude acquired while sitting or standing at lessons or even in playing games, must be carefully inquired for and forbidden. Some other attitude or game which rectifies the faulty position thus produced should be substituted. Any optical defects such as myopia, should receive treatment; adenoids or enlarged tonsils should be removed. Mechanical exercises should always be advised with the view of strengthening the muscles generally and of restoring the tone of those to whose failure the curvature is due. They should be practised daily for ten minutes to half an hour at a time in the late afternoon; immediately after the child should lie down for a rest. Dumbbell exercises may also be performed on rising in the morning for five to fifteen minutes. The dumbbells should not exceed a pound in weight at the outset; as the patient becomes more accustomed to the exercises the weight may be increased, as may also the length of time during which the exercises are performed.

(a) *Cases in which the curve can be obliterated:*

Here the prognosis is good, as the muscular apparatus is probably alone at fault and no bony or ligamentous changes have as yet occurred. The object of the treatment therefore is to strengthen the back muscles and thus enable them to perform their function of maintaining the spine in the erect posture. One of the most important ways of doing this is by suitable exercises. A multitude of exercises have been advocated for the treatment of these cases, many of which are extremely complicated. There are, however, no specific exercises for the cure of this condition and the surgeon can easily design efficient ones for himself by observing the changes that have occurred and by the muscles that are at fault, ordering movements which will bring into play the defective muscles and mechanically rectify the physical changes in the trunk. These exercises should always be carried out in the presence of some one who will see that they are properly and regularly performed for the requisite length of time. The simplest plan is for the surgeon to supervise the first performance of each group of exercises as they are taught and to point out to the gymnastic master or to the parents the exact manner in which they are to be performed. It is well to teach a new set of exercises at each séance, or each alternate one, so that the patient's interest may be stimulated as much as possible and when the entire series has been taught, the performance should be judiciously varied. The exercises should be planned so that they are carried out first in the horizontal, then in the sitting and finally in the standing position, as the muscular strength improves. An important point is that many of the exercises are performed against resistance, the surgeon or some form of elastic apparatus opposing the action of the muscles. After the exercises are over, the patient should recline upon a couch in the prone position for at least half an hour. The period for which the exercises are performed may be gradually increased, if they are proving efficient and no fatigue is produced. At the end of a month or six weeks from the beginning of the treatment, after the simple exercises designd to improved the muscular system generally have been thoroughly learned and properly practised, the surgeon should ascertain what effect has been produced upon the curvature. Should it be found, as it probably will be in early cases, that the curvature has almost disappeared and that the patient can maintain the erect posture without any difficulty, little else is required beyond continuance of the treatment already adopted.

The object of postural treatment is to restore the spine to its normal condition, or even to slightly overcorrect the deformity. The posture employed must be adapted to the individual case, only those being chosen which correct the deformity completely. For example, the following postures will be found useful for a patient having a dorsal curvature which is convex to the right and has compensatory cervical and lumbar curves which are convex to the left. The head is carried well back and held erect. The patient then places the left hand at the back of the neck, with the fingers over the spine and the thumb resting about the middle of the sternomastoid, thrusts the elbow forward and to the left so the scapula is drawn away from the middle line. This exerts traction on the rhomboids and tends to pull the spines of the dorsal vertebrae to the left. The patient's right hand is now placed upon the right side of the thorax, the fingers behind and the thumb forward and makes firm pressure over the convexity of the dorsal curve, while the left arm and elbow are kept well forward. The body is now held rigidly in the improved position that this posture produces while an attempt is made to correct the lumbar curve by separating the right leg from the left by a short step outward so that the right side of the pelvis is depressed. The rotation of the bodies of the vertebrae may now be corrected by taking a short step forward with the left foot in order to twist the lumbosacral joint to the right. While the patient maintains this position, flexion and extension of the spine should be carried out, the head being alternately flexed with the rest of the trunk and kept extended by fixing the eyes on a distant object. Another excellent posture is that in which the patient stands erect with the hands on the iliac crests and makes forcible pressure downwards, as if to push a tight garment toward the knees. This makes traction upon the spine and straightens the curve out; flexion and extension exercises are then carried out.

These exercises are first performed as directed, and as the patient becomes accustomed to them and can perform them without fatigue it is useful to have them performed against resistance, the simplest way of doing which is to instruct the attendant to oppose the movements which the patient is endeavoring to carry out, gently at first and with gradually increasing force as the muscles grow stronger. These movements are only suited for those cases in which there is no permanent distortion of the spine—that is to say, those in which suspension of the patient causes the spine to become perfectly straight. As these exercises produce their effect and obliterate the curve, they may gradually be abandoned in favor of more simple home-drill exercises designed to improve the muscular system generally. These should be practised daily for a long period.

Mechanical supports are never necessary in this group of cases. Care should be taken to see that the patient does not wear stiff stays. The utmost that should be permitted are corsets without bones.

(b) *When the curve can be improved but cannot be obliterated:* The treatment of this class is most difficult, because the affection has lasted long enough for bony and ligamentous changes to have occurred which prevent complete restoration. The treatment, therefore, must have the double object of straightening the spine as much as possible and providing against subsequent relapses. The exercises employed to minimize the curvature are similar to those for the group just described, but they should be persevered with more energetically and should be carried out for a longer time.

Spinal braces of many varieties have been advocated. They should be employed in cases in which the curvature shows signs of increasing in spite of vigorous treatment on the lines just mentioned, or in those in which the pain is severe and the weakness of the muscles excessive. Even then the support should only be worn occasionally during the day and should be as light as is consistent with efficacy. It should be made of light steel bars

taking purchase from a pelvic band and should be furnished with suitably fashioned springs so directed as to apply pressure at the requisite spots, which are generally the convexity of the curve and over the angles of the ribs where they are rotated backward. The apparatus should be so fashioned as only to support the spine when it is in a position of rest; that is to say, it should not be sufficiently tight fitting to keep the spine immovable and therefore interfere with the proper action of the back muscles. At night no apparatus should be worn, attention being mainly directed to the posture in which the patient sleeps. Plaster jackets, applied while the patient is in suspension, have proven of great value in a large number of cases. These jackets are applied at regular intervals, during which time the deformity is gradually corrected.

(c) *Cases in which the curvature cannot be diminished by suspension:* In these cases such severe changes have occurred in the spinal column that it is hopeless to attempt any rectification, and the utmost that can be accomplished is to prevent the affection from increasing and to treat any symptoms, such as pain, etc., that may be complained of.

Summary and Conclusions: 1. Attention to posture should be instituted as soon as children begin to walk.

2. The idea that all faulty postures will be outgrown if left to themselves is a fallacy.

3. Using one side of the body in play or work should be discouraged. Children should be taught to use both sides efficiently.

4. Especial precautions should be taken in rickets, osteomalacia, and other conditions in which there are a deficiency of lime salts.

5. Proper feeding, fresh air and avoidance of sedentary habits, too many accomplishments, poorly fitting clothing, clothing suspended from the shoulders will in a large number of instances obviate the occurrence of faulty attitudes.

6. Proper measures instituted early will in a vast majority of instances obviate many hopeless deformities.

CHILD HEALTH IN EUROPE.

By E. M. JOSEPHSON, M.D.,

PARIS.

PHYSICIAN TO THE AMERICAN RED CROSS.

Never has there been more keenly realized than at the present time the profound effect of war upon succeeding generations and the dependence of the future of the nation upon the welfare of its children. This is attested by the fact that even in the early days of the war, when there were so numerous and pressing matters claiming public attention, many of the lands spared the time, energy and funds to organize bodies to care for the rising generation. As the struggle became drawn out, and the nations exhausted, the problem grew to exceed the resources of the people, and the lands were weighed down by the added sorrow of a gaunt, starving and stunted army of children and orphans. With the return of peace, some of the nations made a rapid recovery and turned with the keenest interest to welfare of their future citizens, whereas others found the health of their children even further injured by the deprivations of the first year of the peace.

At the present enough time has passed so that a rough general picture of the disastrous effects of war upon the child health of the various nations of Europe may be secured. In the present paper the writer has attempted to outline the more serious effects of the war upon the child health in representative countries of Europe and to outline briefly some of the measures which have been taken to preserve life and to build up a sturdy child population.

France.—The children of the occupied region of France, especially those over 6 years of age, suffered severely from malnutrition. Studies on thousands of children of the district of Lille made in May, 1920, showed that 87, 91, and 93 per cent. were below average weight at 12, 13, and 14 years respectively. At 12 years of age 84 per cent. were under weight, and at 13 and 14 years 86 per cent. On the other hand, the children between 7 and 9 years were in better condition. These retardations were reflected in the intellectual development of the children. Mental tests showed that children between 10 and 13 years were retarded on the average one-half year.

Numerous activities were undertaken to remedy these conditions as soon as the region was free of the invader. The most striking results obtained from the activities undertaken by various organizations were secured in the summer camps. It is reported that, in 1920, an average of 75 per cent. of the many thousands of children who were in camp gained in weight, that the average gain in height was 2 cm., and that 75 per cent. showed a marked mental improvement. The lasting benefit is attested to by the fact that 80 per cent. of them had no illness which required absenting themselves from school during the following year. By efficient postnatal care the Consultations des Nourrissons, organized under the auspices of the Comité d'Assistance, infant mortality has been markedly reduced in the liberated region during the past year.

During the years of the war and in 1919 there existed a milk shortage of serious proportions. In spite of the fact that the population of Paris was increased, the amount of milk supplied to Paris was reduced 50 per cent. Various measures were effectively taken to overcome this shortage, among which were ordinances which prohibited the use of milk for fattening calves, the prohibition of the manufacture of cream cheeses, the prohibition of the sale of milk in the cafés, and provision for the supply of milk to patients at the pharmacies on the prescription of physicians.

Vital Statistics: The birth rate in France has for many years been comparatively low. In 1911 the number of deaths was higher than the number of births. In 1912 and 1913 there was once again a natural increase, which in 1914 and throughout the war was replaced by a birth deficit. In the years 1911 and 1915 there was an average birth deficit of 6.7 per thousand. The natural increase of the year 1920, 3.6 per thousand, is, however, the highest reported since 1865.

Infant mortality has been fairly high in France throughout the past decade, the lowest figure being 104 per thousand births in 1912, and the highest during the war period, 141 per thousand in 1915.

The number of stillbirths and illegitimate births kept pace with the varying birthrate.

Czecho-Slovakia.—Czecho-Slovakia is chiefly an industrial State, and its agriculture, while important, does not yield sufficient foodstuff for the population. Industrial depression and a heightened cost of living have contributed to much suffering. The tuberculosis death rate is high and a large number of children have the disease. There is also a high incidence of eye diseases, which calls to mind the recent experimental studies on the relation of eye diseases to malnutrition.

Vital Statistics: There has been a steady fall in the birth rate of Moravia from an average of 36.8 per 1000 in 1881 to an average of 12 per 1000 in 1918. In the year 1919 the birth rate rose once again to an average of 19.8.

The infant mortality rates of Bohemia, Moravia, and West Silesia for the years 1911 to 1919 have averaged about 180, 186, and 192 per 1000 births respectively. The average of Czecho-Slovakia has been about 186 per 1000 births, which means over 50,000 infant deaths a year.

During the same period Moravia and Bohemia had a tuberculosis death rate of 328 per 100,000 higher than that of any other of a list of nine civilized nations. The total death rate has been proportionately high. A fairly constant natural increase of the population in these regions, averaging between the years 1881 and 1915 about 8.9 per 1000, was converted in the years 1915 to 1918 to a birth deficit which in the later year amounted to 11.3 per 1000. In 1919 there was once again a natural increase of 1 per 10,000 in Bohemia and 4.7 per 1000, a fairly marked improvement.

TABLE I.

Czecho-Slovakia—Infant Mortality Deaths per Thousand Live Births, 1913-1919

	1911	1912	1913	1914	1915	1916	1917	1918	1919	Aver.
Bohemia	197	181	175	175	215	186	178	188	132	180.5
W. Silesia	206	190	180	184	226	207	180	198	148	192
Moravia	...	...	184	178	228	196	183	198	134	186

Austria.—There are few lands in which the breakdown of the economic system has been so complete as in Austria. The very poor and many of those formerly well to do are equally affected. This state of affairs has seriously affected children of all ages and of all classes of society. In addition to the influence of undernutrition upon growth and development, the marked under nutrition of the mothers has had a telling effect on the newborn.

Studies made by Dr. T. Weiss on babies born between 1916 and 1919 showed the following: (1) The weight of all young babies was 15 to 20 per cent. under normal. (2) Children between 1 and 4 years averaged 33 per cent below normal weight. Of the children of the poor and middle classes, born during that period, 90 per cent. show more or less marked signs of rickets and anemia.

The prevalence of rickets and anemia is in part attributed to the extreme scarcity of fats and milk at that time. The milk supply of the city of Vienna is at the present time totally inadequate. For a population of 1,800,000, representing almost a third of the total population of the present-day Austria, there is no more than 60,000 liters of milk available, of which the greater part is adulterated. In the summer, half of this available supply is soured and unfit for infant-feeding by the time it reaches the market. This amount of milk is considerably less than a fifth required by the city. Various causes are assigned for this state of affairs. The low price fixed by the government for the sale of milk makes it unprofitable for the farmers to market it, and leads them to prefer to feed it to the cattle. In addition, lack of fodder tends to cause a reduction in the number of cattle in the country. The American Red Cross is interested in this problem and is engaged in remedying the situation through a cooperative arrangement for the supply of fresh milk.

A survey of the children under 6 years of age in Vienna made by the Central Committee for Child Welfare in October, 1920, revealed that among 83,500 of the 110,000 youngsters in that city 40 per cent. were badly undernourished, 10 per cent. very badly undernourished, and only 10 per cent. well nourished.

An interesting effect of the milk shortage is the marked reduction of the infant mortality due to intestinal diseases in Vienna in 1920, due in part at least to the fact that the mothers were forced to nurse their babies.

A survey of children between the ages of 3 and 14 years made in the city of Salzburg in the first half of March, 1920, revealed that 3,455 among 4,169 children were undernourished. The children were classified according to the Von Pirquet method, and the survey is illustrative of the state of affairs in the large cities and the industrial centers of Austria. On the other hand, some of the smaller towns, such as Lend, conditions of child health are fairly good.

The study of the vital statistics of Vienna is of real interest in connection with our topic.

Birth Rate: Between the years 1914 and 1918 the number of live childbirths in Vienna steadily dropped from 36,442 to 19,257 or 52.8 per cent. The decrease of legitimate births (43 per cent.) was less marked than that of the illegitimate (58 per cent). The number of stillbirths also dropped in the same period from 3,771 to 2.517 or 33 per cent. With the return of peace in 1919 the birth rate once again began to rise.

Infant Mortality: Though the number of infant deaths in the first years dropped numerically from 5,074 in 1914 to 2,941 in 1918, the average rate of infant mortality varies only slightly above the average prewar rate, ranging between 12.27 and 15.28 per cent. The drop in the actual number of deaths is attributable to the lowered birth rate. The rate of mortality of legitimately born infants was uniformally lower than the pre-war rate, ranging between 12.27 and 13.08. Possibly the more general nursing of the infants by their mothers accounts for the above-mentioned facts. This reduction is counterbalanced by a steady rise in the death rate of the illegitimately born, which rose steadily from 16.02 per cent. in 1914 to 23.07 per cent. in 1919.

Child Mortality: The figures of mortality of children between 1 and 5 years of age for the period 1914 to 1919 average slightly higher than those of the prewar period, about 2,018 as compared with 1,984 for the years 1912 to 1914. Taking into consideration the lowered birth rate, this figure represents an increase of 30 per cent. The mortality of children between 5 and 15 years was uniformly

higher during the war, averaging 1,426 for the years 1915 to 1919, an increase of about 34 per cent.

General Death Rate: The general mortality as well as the mortality from tuberculosis rose during the above-mentioned period.

Natural Increase: During the war 1915 to 1919 the natural increase of prewar days was replaced by a birth deficit, resulting in a depopulation of 100,000 or about 5 per cent. Since 1919 there has been a steady improvement.

Poland.—The miserable plight of the children of Poland in the latter years of the war was one of the most pitiful consequences of the struggle to be found in all Europe. The country was twice swept by two advancing and retreating armies, each completing the destruction that the other had left undone. A survey of the health of the children up to 6 years living under these conditions, made by Dr. Thaddeus Kopee in 1917 and 1918, shows the following:

1. The number of well-nourished children dropped from 60 per cent. of the total children at the age of one year, to an average of 40 per cent. in the succeeding years. The number of emaciated children rose from 15 per cent. in the first year of life to an average of 30 per cent. in the succeeding years.

2. The average weight of the children was 23 per cent. below normal at one year of age, and dropped to 35 per cent. below at five years. The minimal weights recorded were 50 to 60 per cent. below normal.

3. Starvation edema was present in 1 per cent. of the children in the first year of life, 13 per cent. in the second year, 10 per cent. in the third, 8 per cent. in the fourth, and 7 per cent. in the fifth.

4. The retardation in the development of the children consequent upon malnutrition, delayed their commencing to walk. Among the children 4 to 5 years old, 4 per cent. had never been able to walk. In addition to these children who had never developed the power to walk, there was also a large number who because of feebleness, disease, or maldevelopment, had retrograded and had lost the ability to walk, this number amounting to 27 per cent. of the total at 4 to 5 years of age. One-third of all the children 5 years of age were unable to walk.

5. Of the children 5 years of age, 26 per cent. showed signs of tuberculosis.

Poland is essentially an agricultural country, and with the return of peace ample crops have insured a good supply of food. The following is a survey made of the physical condition of children from a number of orphanages in several sections of the country in April, May and June, 1921. Height, weight, and physical condition were determined, and the children were classified as: A—well nourished; B—fairly nourished, and C—poorly nourished. As a rule it was noted that the boys were better nourished than the girls. The findings show a marked improvement in conditions as compared with Dr. Kopee's survey.

	A.	B.	C.
Station 1.			
April	61.11 per cent	32.65 per cent	6.27 per cent
June	67.24 per cent	28.67 per cent	4.08 per cent
Station 2.			
April	57.77 per cent	33.00 per cent	9.25 per cent
June	65.32 per cent	27.87 per cent	6.68 per cent
Station 3.			
April	60.63 per cent	32.08 per cent	5.85 per cent
June	58.86 per cent	34.86 per cent	6.48 per cent

Birth Rate: The birth rate of Poland has steadily dropped between the years 1891-1918 from 40 per 1000 to 14.6 per 1000. During the years 1919 and 1920 there was an increase in the number of births, the figures being 26.7 and 29.7 per 1000.

Infant Mortality: Infant mortality in Poland during the period 1904-16 was uniformally high, averaging about 25 per cent. of the total number of deaths. In some districts the rate was very high. In Dabrowa Gornoza, the infant mortality, and in the Province of Plock, 37.4 per cent. It must be remembered in connection with these percentages that the general mortality during the same period was also high.

Natural Increase: The natural annual increase in population due to the excess of births over deaths dropped from 17 per 1000 in 1891 to 6 per 1000 in 1914. In the following years there was a natural decrease which in 1917 amounted to 24.2 per 1000. During the years 1919 and 1920 there was once again a natural increase of 3.7 and 9.4 per 1000 respectively.

Relation of Infant and Child Mortality to the Size of Families.—The oft-repeated observation of the increase in infant and child mortality with increase in the size of families is made once again, in an exaggerated form, in two cities of Poland—Warsaw and Lodz. The records of both of these cities show a steady rise in infant and child mortality with increase in the size of families, ranging from an average of 17.3 per cent. in families with three children to 56.2 per cent. in families of 12 children or over.

Conclusion.—There has been in the last year a marked improvement in child health, in the countries considered, as compared with conditions existing during and shortly after the war. This is also true, with several exceptions, of all the European countries. A gradual return to normal conditions and the general help of the more fortunate lands of the world have combined to effect this recovery. The widespread keen appreciation of the seriousness of the child-health problem promises much in the way of future improvement.

THE BLADDER BOGY.*

By ALEXANDER NICOLL, M.D., F.A.C.S.,
NEW YORK.
SURGICAL DIRECTOR, FIRST DIVISION, FORDHAM HOSPITAL.

It seems to be definitely established that the percentage of recurrences after operation for hernia is larger than it should be; it seems equally well established that recurrences after operation for direct hernia are not only more frequent than they should be but are also more frequent than are recurrences after operation in indirect hernia. Many operations have been devised, most of them variations of the familiar Bassini method, to do away with this most unpleasant feature of the treatment of this condition. I should like to call attention to the fact that most of these methods—many of which have very excellent features—are directed toward the repair of the musculature of the inguinal region. So general appears to be this attitude toward the radical cure of hernia, namely that muscular recon-

*From the Clinic of the First Surgical Division of Fordham Hospital, New York City.

struction is the main point in the treatment, that I do not believe that a word of caution is amiss. The first step in the cure of the hernia should be—and is—the proper reconstruction of the parietal peritoneum at the point where the hernia occurs; whether this reconstruction be well done, or half done, determines the success or failure of the operation in a very large percentage of cases—without regard to the type of muscular reconstruction employed.

Ochsner has called attention to the fact that a complete removal of the sac and its fatty appendages will result in a cure in many cases of a certain type of hernia—the femoral. A certain very excellent surgeon of this city—who may not wish to be quoted—has stated that after the complete removal of the sac in the indirect variety of inguinal hernia it did not matter what variety of muscular repair was used—the patient would be cured. This appears to me to be an unsound, and extreme, view, but it would seem that there must be some basis for it. It would appear to be much safer to view the matter from the standpoint that both peritoneal and muscular repair are necessary, and that to insure against recurrence both must be well done. It is because I have felt that this matter of peritoneal repair is often slurred, and is frequently, in discussions, relegated to a very minor and unimportant position, that the present remarks are offered.

The necessity for the high ligation of the sac is well recognized. It is essential that the sac be ligated so high that the site of the "neck" be flush with the contiguous parietal peritoneum. If there remain any portion of the funicular process it is apparent that intraabdominal force will be directed at the newly repaired spot, and that this persistent funicular process will augment the intraabdominal force or pressure by supplying it with a wedge with which to breach the new-formed internal inguinal ring and inner wall of the new canal. The word "neck" is enclosed in quotation marks to call attention to the fact that as generally used and ordinarily conceived the word is misleading; to look upon the hernial sac as a process of peritoneum which resembles in some ways the finger of a glove, and to consider that it departs from the parietal peritoneum in much the same way as the finger of a glove leaves the body of the glove—abruptly—is incorrect. The fundus of the sac is largely determined by its contents, both as to size and shape; that portion of the sac which lies within the inguinal canal is limited and shaped by the walls of the inguinal canal, but that portion of the sac which lies within the internal ring is shaped by two factors: (1) the original shape of the performed peritoneal process itself, which originally may have had a sharp enough inner mouth, *plus* (2) the acquired shape, the result of the persistence of the hernia which has caused a bulging at the internal ring, in which the surrounding peritoneum takes part. Thus we see that superimposed (from the abdominal side) upon the original neck of the sac there is present a funnel-shaped process of tissue composed of the parietal peritoneum in the region of the internal ring. To destroy this funicular process should be the aim of the surgeon as the *first* step in the cure of the hernia. These remarks apply to indirect hernia in general and, with a little change in phraseology to fit the difference in anatomy, to direct hernia as well.

In the matter of the reconstruction of the peritoneum in indirect hernia the problem is not a difficult one; the ligation of the sac high up and flush with the contiguous parietal peritoneum is a mere matter of proper dissection carried out safely and with assurance, because the operator meets with no anatomical peculiarities to render him uncertain, or confuse him. It is a simple matter of familiarity with the tissues in which the surgeon works. With the problem of the high ligation of the sac in direct hernia, however, confusion enters; far be it from me to suggest that the occasional herniotomist is not so sure of his tissues and so certain of his anatomy here as he should be! Perish the thought! Nevertheless, such is the case.

Observation of the work of many men—many *good* men—coupled with my own experience until recently, has shown me that the herniotomist is at home at the level of the peritoneum when dealing with indirect inguinal hernia, but that this structure is not so well known to him when working toward the median line at the lower and inner end of Hesselbach's triangle. A comparison of the peritoneum in the region of the necks of the sacs of the indirect and direct hernias serves to bring to light many well known and significant differences; two alone are sufficient to dwell on here—the vascularity, and the presence of properitoneal fat.

In indirect hernia the sac is composed of thin peritoneum and little or no properitoneal fat; also the vascularity is nil. The direct hernial sac is composed of the same thin peritoneum, but with a thick deposit of properitoneal fat which is definitely and markedly vascular. Ligation of the sac of the indirect hernia is usually accomplished with greater efficiency than ligation of the sac in direct hernia; recurrences are less frequently found after operation for indirect hernia than after operation for direct hernia; I believe that these two facts have much more than a coincidental relation. Ligation of the sac in direct hernia by the usual method—transfixion—results frequently in bleeding from the vascular properitoneal fat; a simple ligature thrown about the sac, without transfixion, fails to hold in the soft and slippery fatty tissue, with the result that the sac pops open and must be again isolated and closed. If this popping open of the sac occurs at the time of operation it is merely annoying and results in delay; if it occurs after the muscular repair has been made the results may be much more serious, an actual localized evisceration being the certain outcome. The method of choice should be the suture of the sac, in the same manner that closure of the peritoneum is secured in any laparotomy—any *other* laparotomy; and greater security is obtained if the closure is made with some form of hemostatic suture such as the lock-stitch. So much for the method of closure of the peritoneal sac; now as to the *place* at which such closure should be made.

Again we must consider that we are at a fundamental stage of the repair of a hernia and that the sac must be closed flush with the contiguous parie-

tal peritoneum. It appears simple, and it is simple —or would be but for the introduction at this point of the Bladder Bogy! The mental hazard of golf applied to herniotomy! A mental hazard and a bogy for the reason that in nine cases out of ten it does not exist. In at least nine cases out of ten the bladder is *not* in such a position as will permit it to be injured in the closure of the peritoneal sac of a hernia.

The picture I have observed so many times is about as follows: the herniotomist has reached the stage of closure of the sac; he notes the apparent thickness of the peritoneum—in reality the peritoneum is no thicker but appears so because of the deposit of properitoneal fat—he notes the vascularity, remembers that the bladder is sometimes found in the sac or forms part of its wall, realizes that the peritoneal attachment of the bladder is not unlike the picture presented by the *normally* thick sac, points a casual finger in a general southeasterly direction as he says, very firmly, "that is bladder," and proceeds to close the peritoneum in such fashion as to encroach as little as possible on the structures toward the median line; he permits himself to forget that the flush closure of the peritoneum is an *essential* part of the operation for the *cure* of hernia, and feels that he has done well in avoiding injury to the bladder, which usually has been in no danger of injury for the good reason that it has not been present at the spot under suspicion. The above is written without thought of carping criticism; it is not a product of the imagination but rather reminiscent in character; it combines observation with introspection; it is written with feeling.

"He jests at scars who never felt a wound."

A very simple and useful expedient is now in use on the First Division of Fordham Hospital; one which does away with uncertainty, allows us to proceed with assurance in treating the neck of the sac in direct hernia, and prevents injury to the bladder in the infrequent case in which this structure actually obtrudes upon the field of operation. Before operation in all cases of direct hernia, and during operation in all cases in which the presence of the bladder is suspected in relation to the sac, the bladder is moderately distended with boric acid solution.

We believe that this simple procedure is of definite value in that it permits us boldly to suture the neck of the sac in such manner that the resulting suture line shall be flush with the parietal peritoneum, and at the same time outlines the bladder so clearly that injury to it is as nearly impossible as it should be. We have been much interested to find that the outline of the bladder, in these injected cases, comes nowhere near the neck of the hernial sac, in at least nine out of ten cases, and could not be included in a ligature or injured with a suture placed in such manner that the resulting ligation or suture-line would be flush with the parietal peritoneum. In the tenth case there is not a momentary doubt in the mind of the surgeon as to whether the bladder is present or not, and injury is unthinkable.

ACUTE INFECTIONS INTO THE SEBACEOUS GLANDS AND HAIR FOLLICLES OF THE NASAL VESTIBULE.*

By LEE M. HURD, M.D.,

NEW YORK.

That the common and usually trivial boil in the nose can suddenly terminate fatally by extension of the infection through the venous channels to the cavernous sinus, is not realized by the laity and not, I fear, any too well recognized by many physicians. When only two textbooks on rhinology mention furuncles and do not hint, even, that there might be grave complications, and also, when only a few textbooks of General Surgery mention the subject, it is no wonder that this condition is considered so lightly. One striking fact in the literature is that most of the cases are only recognized when they are well advanced and hopeless, and then usually by the consultant who reports the case.

If anything is to be done to cut down the mortality from these infections it will be by early recognition that the cavernous sinus is threatened and very prompt measures taken to prevent it.

Etiology—The predisposing and exciting causes are the same as those of furuncles elsewhere on the skin, plus bad habits of picking the nose and pulling out the vibrissae, and infection from the nose passing through the vestibule. The staphylocossus is the common organism but it may be streptococcus.

Symptoms—Pain, tenderness, redness and circumscribed swelling in the vestibule, sometimes showing through to the external skin, are the usual symptoms. Later, softening at the centre with rupture and discharge of pus and slough "core" occur, followed by prompt healing. This trivial discomfort may suddenly become extremely serious by extension to the cavernous sinus; this may be due either to attempts at opening, usually with a dirty needle at home or by squeezing and rupturing nature's barrier, thus driving the infection into the less resistant subcutaneous tissue, or picking the head off the furuncle with a dirty finger nail, or, by too free incision, opening up new avenues outside nature's barrier, or in other cases, it seemed to have traveled the venous channels as a result of what we term lack of resistance to infection.

Diagnosis—A furuncle or collection of them should offer no difficulty; in fact, the patient usually has correctly diagnosed his red, swollen, painful nose as a boil and usually has operated with a needle and squeezed the same, seeking medical aid because it is getting worse under his treatment.

Complications—There may be sloughing of the inferior lateral cartilages. The cavernous sinus may become infected more frequently than is generally thought and it is one's duty to forestall this calamity, if possible, for as is well known, the mortality of cavernous sinus thrombosis is practically 100 per cent.

It behooves us to manage the case so that the infection will not reach the sinus, if it can be avoided.

Seeking light from the literature, one feature of

*Read before the twenty-sixth annual meeting of the American Academy of Ophthalmology and Oto-Laryngology, held in Philadelphia, Pa., October 17, 1921.

nearly all the reports is that the cases were not seen until too late and diagnosis made still later. Also, that vestibular furunclosis is not well classified; cases are found in with other case reports. Again, as to when and how the primary focus was handled is not clear enough to draw any constructive deductions, whether the cavernous sinus thrombosis came from neglest or mismanagement, or was so fulminating that nothing could be done.

With a vestibular infection a tentative diagnosis of cavernous sinus thrombosis should be made on the appearance of any of the following eye or orbital signs which should be considered very suspicious: Swelling of the lids, chemosis, pupillary changes, deep seated headache, beginning ptosis and exophthalmos, lacrimation, congested retinal veins, symptoms of sepsis. Later, when ophthalmoplegia, pronounced chemosis, edema of the lids, and exophthalmos plus cerebral and septic symptoms develop, the case is hopeless and it usually is only a matter of a few hours before the opposite eye indicates that both cavernous sinuses are thrombosed and dissolution is near.

Treatment—Though most vestibular furuncles are trivial affairs, it should ever be remembered that, from poor resistance of the patient or bad management, a seemingly trivial affair may explode with fatal results. When the patient is fortunate enough to be seen early, my procedure is to use wet dressings inside and out and, as soon as there is evidence of pointing, to make a small incision at this place and never to go outside of nature's barrier; by applying suction to draw out the infective material; to fill the cavity with bismuth paste between treatments, and never to squeeze the swelling which might cause rupture into the subcuticular tissue where the chances of tissue resistance are much lower. This treatment seems to be much better than extensive incision and expression which is so often mentioned in the literature of the cases which later developed cavernous sinus thrombosis. I have treated a number of cases in which the local involvement was severe, yet with a small incision entirely within the barrier and suction, they have recovered without complication except sloughing of the inferior lateral cartilage in three cases.

As this infection extends along the anterior facial, angular and superior ophthalmic veins to the cavernous sinus above and perhaps by the deep facial vein and pterygoid plexus below, it seems rational to ligate the anterior facial vein near the inner canthus, as *Bullock* (1, 2) reports in one successful case of upper lip infection, and also to ligate the anterior facial vein above the deep facial vein at the anterior border of the masseter muscle the minute you feel that the infective area is increasing instead of diminishing, or, if there is the slightest orbital or ocular symptom of cavernous involvement.

As lateral sinus thrombosis sometimes recovers, similarly, why may not the cavernous sinus overcome a slight infection if further infective supply is stopped? At least facial vein ligation is a simple procedure and may save the patient's life. As up to the present time surgical attack of the cavernous sinus for anterior infections has failed to cure (3, 4, 5, 6, 7, 8) and has in a few incidences even failed to open the sinus, further technical experience and earlier diagnosis will probably produce better results in the present hopeless situation by one of the different methods.

A BIOCHEMICAL EXPLANATION OF THE SILICA MOLECULE.

By P. R. Vessie, M.D.,

Gowanda, N. Y.

The silica molecule of the human cell has an important function to fulfill in many circumscribed infections such as abscesses, fistulæ, boils, carbuncles and tubercles. By an ingenious method this inorganic constituent limits the spread of infection and is a means of supporting the leucocytes in their combat against invading bacteria.

The Destiny of Silica-Bearing Food.—With the exception of oxygen, silica is probably the most widely distributed and abundant of elements.* Friedenwald and Ruhräh[1] remark that it is present in many vegetables, but the part played in the economy is unknown. Many years ago, Liebig, the chemist, advanced a law that an absolute amount of tissue-salts, such as silica, is necessary to maintain the processes of nutrition. Kunkel[2] detected exceptional quantities of silica in the human pancreas, and several authors have since presumed that this organ gathers the silica intake, releasing it into the circulation when it is needed, just as the liver acts as a depot for the distribution of iron (hematin) and the thyroid for iodine (thyroxin). At any

*In the classification of elements in the human economy carbon, silica, titanium, and zirconium are grouped in one family because of their close relationship.

rate, the knowledge of silica as an *essential component of connective-tissue* was established in the early days of organic chemistry. Schulz[3] in 1901 reported the silica content of this tissue as being of constant proportion[4].

A Basic Theory on the Action of Silica.—When Schuessler[5] founded in 1872 an independent biochemic school of therapy he reasoned that a disturbed silica molecule of the connective-tissue cells would result in disease, such as an abscess formation, and that by supplying silica to these tissue cells their function would become restored, thus, causing the collected pus either to be carried off by the lymphatics or to ripen and open spontaneously. But this theory does not explain the method of action. In the revised editions of this work there is no mention of the tactics of the defending leucocytes and the fate of the bacteria.

The Effect of Bacteria on Silica.—That bacteria shatter the neutral salts in the molecule is conceded. As proof, Klett[6] ascertained, when testing many products in the presence of bacteria, that *bacterial enzymes have the chemical power of reducing sodium silicate.* However, no biochemic interpretation was attached to this finding by Klett or any other investigator.

Silica As a Protection Against Tubercle Bacilli.—Kühn[7] observed that guinea pigs are rendered immune to tuberculosis after receiving injections of silicic acid. Some years ago Wilde[8] recommended a solution of sodium silicate as an ideal form of treatment. Recently Gonnermann[9] reported brilliant results with silica preparations in tuberculosis.

With these facts and opinions as a guide we will attempt to formulate:

A Biochemic Theory.—1. Silica is widely scattered in essential food products.

It is absorbed and assimilated by the human tissue cells.

While found by analysis in all structures and organs of the body it is notably present in the connective-tissue cell.

2. "Bacteria require the *same kind of food*, which they select, assimilate, and excrete in much the same way *as the cells of the higher animals.*" (Victor C. Vaughan[10].)

Laboratory methods demonstrate that bacteria have the ability chemically to reduce soluble silica.

It follows that *bacteria may digest the silica molecule* as well as other components of a human cell.

Since silica is the preponderant neutral salt in the connective-tissue cell, bacteria may dissipate it, causing a *famine* of this element at the site of bombardment.

If the human economy has a sufficient supply of silica in reserve, temporary silica starvation at the point of bacterial attack is immediately remedied by a *replacement of silica molecules.*

3. On the other hand, when nature fails to act with such favorable promptness in regrouping displaced or lost silica molecules, certain types of pus-producing bacteria (staphylococci) may gain a foothold at a focal point within the body.

In the event of suppuration, a *defensive barrier* of connective tissue, loaded with silica molecules, is formed around the nucleus of pus-organisms to resist their systemic advance.*

(*a*) This *fibrous wall* which encysts an abscess cavity of pus cells, bacteria, and debris, (*b*) the area of *serofibrinous exudate* in a boil and carbuncle, and (*c*) *granulation tissue* (connective-tissue cells) in a wound are very *rich in silica.*

Thus, pus-forming bacteria become less potent from *want* and even perish by *self-destruction* when successfully *pocketed by a silicated zone* ("silication").

4. Since a "tubercle" in lung tissue is rarely present without pus-forming bacteria, a similar formation of connective-tissue is built up to imprison the tubercle bacilli and associate bacteria.

The "healing" of tubercles is effected by a new formation of firm connective-tissue, essentially rich in silica. A fibrous capsule shuts off this formation from neighboring tissues, preventing the tubercle bacilli from escaping through blood vessels.

Therefore, an active case of *tuberculosis* faces a condition of *silica hunger* and "silication" is impossible because the bacteria continue to feast on the systemic supply of silica.

Silica appears to be an actual protection to human life. Hence, the term "healing by silication" in the instance of a tuberculous lesion.

5. If silica is reduced as nearly as possible to an atomic state, for specific example, in colloidal form, it may serve as a remedy.†

Sodium silicate (chemically pure water-glass) is of a colloidal nature and assimilable to form *colloidal silicic acid* (a true colloid). After this simple step, it enters the circulation and combines with bases to yield a highly complex derivative. A chain of silica atoms conjugates with the complex chains of the other elements to compose units in a cell. Silica is probably oxidized to silicon dioxide just as carbon is converted into carbon dioxide.

6. When the silica molecule is distributed it affects the other molecules in greater or less degree. A change in the character of the connective-tissue cell is thereby produced by giving the cell the proper impulse with its own specific substance (silica), the inhibited molecules reset themselves to a normal grouping and speed. An example in point is the exciting influence of thyroid extract in restoring the arrested function of the Thyroid Gland. In the words of Garretson[11], "When one has but to *tickle* the gland, as it were, by stimulation through its own active principle, most glowing results are obtained."

Medicolegal Notes.

Physician's Testimony as to Patient's Declarations as to Cause of Injury Inadmissible.—The Court of Errors and Appeals of New Jersey states the general rule to be that the declarations of a patient as to his symptoms, made to his physician or surgeon for the purpose of treatment, are admissible in evidence, since they derive some credibility beyond that of hearsay from the fact that the patient expects his physician or surgeon to be guided by such declarations in administering remedies and so has an incentive beyond the ordinary obligation to tell the truth. "But when such declarations are made, not for the purpose of treatment, but for the purpose of leading the physician or surgeon to form an opinion to which he may testify as a witness for the defendant, not only is this reason for credibility absent, but instead self-interest becomes a motive for distortion, exaggeration, and falsehood. Hence it is the better conclusion that declarations made under such circumstances are not competent evidence on behalf of the declarant." The rule is approved by Prof. Wigmore on Evidence, who cites the opinion of the Supreme Court of Massachusetts in Roosa v. Loan Co., 132 Mass. 439, holding that the statement by a patient to his physician of the cause of an injury from which he is suffering is inadmissible as evidence of that cause in an action for the injury.

It is therefore held, in a prosecution for procuring a miscarriage, that a physician's testimony as to the woman's statement to him, when he attended her, as to the cause of her condition, was inadmissible.—State v. Bruick (N. J.), 114 Atl. 547.

Order for Physical Examination of Plaintiff Should Not Include Blood Test or X-Ray Photograph.—The New York Supreme Court, Special Term, Monroe County, holds that, under section 873 of the Code of Civil Procedure, a physical examination in the nature of a blood test will not be granted in an action for personal injuries. The court says: "The right to a physical examination is purely statutory and should not be extended by construction beyond the intention of the Legislature when the statute was enacted. A blood test involves a puncturing of the human body, and while it may not be attended with any appreciable pain or reasonable apprehension of danger to health, it cannot be said that such a test was within the contemplation of the Legislature when the statute relating to physical examination was enacted. If the examination is to be extended to something not ordinarily understood by that term, it should be left to the Legislature to so provide." The court cited Lasher v. S. Bolton's Sons, 161 App. Div. 381, and Gregory v. Acme Road Machinery Co., 175 App. Div. 473, in which cases it was held that, under this statute, a plaintiff need not submit to have an *x*-ray picture taken on behalf of the defendant.—Hoyt v. Brewster, 189 N. Y. Supp. 907.

Calling One Attending Physician Held Not a Waiver of Privilege as to Another Attending at a Different Time.—The New York Appellate Division holds that, under section 834 of the Code of Civil Practice, prohibiting disclosures by a physician of information acquired in treating a patient, the calling, in a personal injury case, of one attending physician does not constitute a waiver as to another physician who attended the party at a different time. The court refers to the opinion of the Court of Appeals in the case of Capron v. Douglass, 193 N. Y. 11, 83 N. E. 827, a malpractice action, where it was held that where the plaintiff himself, upon the stand, had testified as to what took place with the physician offered by the defendant as a witness, the evidence of such witness should be received, as the plaintiff had waived his privilege. It was also there held that where the evidence of one physician is received without objection, the door is open for the receipt of the evidence of other physicians, who were present at the same time and took part in the same examination. The Appellate Division does not consider the Capron case held any more than that; but the language used has been construed as holding that where one physician is called and describes the patient's condition, another physician who attended him at about the same time may be called by the opposite party to describe his condition at the time when such physician attended him. Before the Capron case the Court of Appeals had decided four cases, the first being Hope v. Troy & Lansingburgh R. R. Co., 40 Hun 438, affirmed 110 N. Y. 643, without opinions, in which it had been decided by the Supreme Court that the calling of one physician did not waive the privilege as to another physician who treated the party at a different time. The Appellate Division does not think the Court of Appeals intended, by its decision in the Capron case, to overrule these decisions and establish an entirely different doctrine, without referring to the decisions. The court says: "It is not unreasonable to suppose that cases might arise where a party would be willing to have one attending physician disclose all he knew about the patient's condition, when at the same time the party would be willing to forfeit all of the benefits which he might derive from his cause of action rather than have another attending physician disclose information which he had obtained in treating the party for the same injury."—Hethier v. Johns, 189 N. Y. Supp. 605.

Mistaken Use of Word "Accident" Instead of "Injury" in Medical Testimony.—In an action on an accident insurance policy, alleging death from blood poisoning from a wound, a medical witness, who examined the insured after the poisoning had progressed from the thumb up the arm, was allowed by the trial court to testify on behalf of the plaintiff that the poisoning was from external means. The Supreme Court of Nebraska, on appeal, saw nothing improper in the admission of that testimony, since the doctor testified that poisoning of that kind in that locality always came from without through an opening in the skin. On cross-examination he was asked, if septicemia had been in the body prior to the injury, whether or not it might not extend to the surface and manifest itself there, to which the doctor answered that he had only one opinion about this case—that the poisoning came from without, from "an accident." It was contended that the doctor was thus allowed to express his opinion that the injury was the result of accidental means, and therefore that the testimony was improperly received. Such an opinion as to a conclusion of fact could not, of course, be received as evidence. The court, however, understood the doctor to mean "injury" instead of "accident," and that he was not attempting to give evidence as to how the injury had been caused, and therefore it considered the answer could not mislead the jury.—Hornby v. State Life Ins. Co. (Neb.), 184 N. W. 84.

Ordinance Prohibiting Hospitals for Contagious and Infectious Diseases in City Held Invalid.—The California Supreme Court holds that a city ordinance prohibiting the maintenance anywhere in the city of any hospital for the treatment of contagious or infectious diseases is wholly unreasonable and therefore not justified as an exercise of the city's police power. "Such prohibition," the court said, "is very different from regulation, and can be justified only on the ground that such a hospital, no matter how well conducted, is a menace to the public peace, morals, health, or comfort. That a well conducted, modern hospital, even one for the treatment of contagious and infectious diseases, is not such a menace, but, on the contrary, one of the most beneficent of institutions, needs no argument. There is not the slightest danger of the spread of disease from it, and this is the only possible ground on which objection could be made to it. We have no hesitation in holding an ordinance prohibiting the maintenance anywhere within a city of an institution so necessary in our modern life and so beneficent to be wholly unreasonable and invalid." The plaintiff, a corporation formed for benevolent purposes, owning and operating a hospital for the treatment of tuberculosis, was held entitled to have the enforcement of the ordinance enjoined.—San Diego Tuberculosis Association v. City of East San Diego (Cal.) 200 Pac. 393.

New York, January 21, 1922.

A MUCH NEEDED STUDY OF THE NARCOTIC PROBLEM.

A RESOLUTION has been introduced into Congress by Representative Volk, who is a physician, calling for the appointment by the Speaker of the House of a committee of fifteen, including therein all the members of the medical profession who are also members of the House of Representatives, to make a thorough inquiry into the subject of narcotic drug addiction in the United States. The scope of this investigation will include all the data available regarding the methods of treatment of addicts by private physicians, institutions, and sanatoria, and the effectiveness of the present laws and their interpretative regulations in the control of smuggling and the abuse of narcotic drugs. The committee as a result of its studies will propose new legislation, if necessary, for the control of narcotic drug addiction.

In the preamble to this resolution it is stated that medical and administrative authorities estimate that there are between one and two million drug addicts in the United States, many of them being ex-service men, and that "many of the rulings of the Federal Government and the provisions of State narcotic laws and sanitary codes of municipalities of the United States point to an organized conspiracy on the part of certain administrators and physicians to drive narcotic drug addicts into established sanitaria purporting to treat and cure narcotic drug addiction." Furthermore it states that medical research has brought out conclusive scientific proof that there are grave physical reactions in the body of an addict deprived of his drug, resulting in acute discomfort, collapse, and sometimes death; that the phenomena of deprivation duplicate those evidenced in cases of infection; and that sera from the blood of animals during drug withdrawal have produced the complete symptomatology of drug withdrawal when given to unaddicted animals of the same species. All these facts, the preamble continues, have been ignored in the administration of the Harrison narcotic law, and in that of various State narcotic statutes and municipal sanitary codes and regulations, "by the issuance of rules and regulations making it impossible for physicians to treat narcotic drug addicts without fear of arrest, indictment, and conviction, or interference and prosecution by the criminal authorities." Such administration, the preamble concludes, has resulted in an increase in smuggling and illicit peddling of narcotic drugs, an increase in addiction, and an exaggeration of evil conditions in the underworld due to the existence of a criminal type of addicts.

If existing conditions are one-half as bad as Representative Volk sets forth in the preamble to his resolution—and everyone knows that some of the evils he depicts do exist—it is time that such a study as the resolution contemplates were undertaken. European authorities are nearly unanimous as to the existence of a narcotic drug disease, but in this country such a theory is vociferously opposed by a number of lay and medical persons, most of them with little or no practical experience in the management of the drug addict. The mass of the profession in the United States knows little or nothing of the real conditions in drug addiction, most of us basing our opinion on the say so of some one whom we regard rightly or wrongly as an authority. It is to be hoped, therefore, that an investigation such as is proposed by Representative Volk can be undertaken and conducted so impartially and be so guided by scientific principles that its conclusions will force themselves for acceptance upon the mind of the profession. It is only so that the question can ever be definitely settled and justice be done to the suffering addict.

INFLAMMATION OF THE OMENTUM.

FROM a study of the epiploitides it becomes clear that three categories exist, namely, the hernial, abdominal, and hernioabdominal. Hernial epiploitis is the better known of the three. To abdominal epiploitides belong postoperative inflammation and inflammation by direct extension, and in particular those following the radical cure of hernia. As to the third category, to which the term hernioabdominal has been given, it comprises those cases in which the omentum is inflamed in both its hernial and extrahernial portion, the lesions often very distinctly predominating in the latter portion. Generally speaking, epiploitis may be regarded as a phlegmonous infiltration, affecting—according to the case—the following forms: (*a*) Congestive infiltration; (*b*) suppuration; (*c*) sloughing; (*d*) fibrous, or fibrofatty infiltration—chronic phlegmon. These forms are almost always accompanied by adhesions. These adhesions play a prominent part in epiploitis, whether associated with phlegmonous lesions or constituting the lesion themselves. They either result from infection or are caused by manipulation or rubbing, which injures the endothelium of the oventum and peritoneum with which it is in contact. Infection is the great factor of epiploitis. It may be endogenous—hernial, or hernioabdominal epiploitis, or exogenous—postoperative. In the latter case the ligatures are unquestionably the

cause of the infection, and this may also arise from contact of the omentum with an infected organ—appendix, ovary, etc.

The symptoms of epiploitis are not very distinct, and the diagnosis is easy only in the hernial type. In abdominal epiploitis the symptoms may resemble those of some other process, such as localized peritonitis, appendicitis, or inflammation of the adnexa, or while in epiploitis from direct extension they become blended with those of the concomitant affection. At any rate, the appearance of a more or less large tumefaction, with rapid development, will lead to a suspicion of the probable lesion; and when under the abdominal parietes a rather thick pedicle in continuity with an inflamed epiplocele is felt a diagnosis of probable hernioabdominal epiplotis may be made.

The evolution of epiploitis following the radical cure of hernia may be divided into three phases of variable duration and intensity: (1) Phase of gastrointestinal disturbances; (2) peritoneal disturbances and appearance of a tumefaction; this tumefaction is sometimes very considerable and seems to belong to epiploitis following ligature of the omentum; and (3) the terminal phase, ending in resolution, suppuration, or fibrous organization. Omental adhesions are of considerable clinical importance. They are useful when they result in walling off pus collections, but more often they are dangerous in that they produce phenomena of occlusion, visceral ptoses, pain, etc. They may sometimes keep up latent foci of infection, whose awakening, on account of the accidents ensuing, may lead one to suspect a return of the affection giving rise to them; and finally, they may seriously complicate the operation. Among the complications to which epiploitis gives rise should be mentioned torsion of the omentum in cases of hernia; while sinuses may result from suppurating abdominal epiploitis.

The prognosis of omental inflammation is in general favorable, but depends largely upon the acumen of the surgeon who correctly interprets the clinical signs and decides upon an opportune operation.

The surgical treatment consists of resection of the omentum in the midst of healthy tissue and reunion by a chain catgut and suture. In cases of abdominal epiploitis, the treatment will vary according to the conditions present—movable or fixed tumefaction, a purulent collection, adhesions, etc. When free and movable the diseased portion of the omentum is to be excised, but when the tumefaction is extensive, solidly fixed, and contains a pus pocket, this latter should be incised and drained. Simple incision of the tumefaction has been known to give good results even when no pus was present. The accidents set up by adhesions require laparotomy, division of the adhesions, and freeing the viscera. When the adhesions protect the abdominal cavity they are to be carefully respected. A later operation may be necessary if they give rise to gastrointestinal disturbances of a mechanical nature.

ARTERIOSCLEROSIS AS A DEFENSE REACTION.

In Humphrey's study of very old, healthy individuals it is stated that the arteries were usually soft. In such cases there is evidently no demand for any defensive reaction on the part of the organism. In healthy old prostatics with arteriosclerosis and high blood pressure, such as often figure in case histories, the hardening of the arteries suggests a defensive mechanism. We are therefore able to visualize two different types of healthy old age in which the first seems decidedly rare and freakish while the second is common and readily intelligible. But while the usual claim is that the arteries thicken to adapt themselves to increased blood tension, there is also the opinion expressed that the increased tension itself is a defense reaction due in part to the progressive loss of arterial resiliency. This view is mentioned by Micheleau in the *Gazette hebdomadaire des sciences médicales de Bordeaux* for November 13, 1922, xlii, 46. The author was associated with Picot, who in his time was an associate of Trousseau, and the clinical traditions which have descended to him cause him to reject all attempts to apply mathematical formulæ to the sick man. In other words, he avoids placing too much trust in an instrument like the oscillometer and blood-pressure apparatus in general. The practitioner insists on an explanation for high tension in the given case; perhaps he is apt to ask why should a man continue to live and enjoy life with a disgracefully high pressure? The author of this article says he has a friend whose measurement for some years has been from 260 to 280 mm. of Hg. The man is 64 years of age and his health is apparently perfect despite the sword suspended above his head.

Since it is a necessity for a certain amount of blood to reach all important organs to insure their nutrition and functional efficiency, especially in the case of the digestive apparatus and the eliminative organs, it seems inevitable that with advancing years and deterioration of machinery the blood must be pumped more vigorously through the circulation, which in turn necessitates a strengthening of the vascular walls. The hypertension in surgical and sthenic fevers is conservative, and when increase of blood pressure is motivated by the presence of toxins in the blood it seems evident that Nature is seeking to expel the latter through the emunctory organs. Owing to the great number of toxic principles which the subject must eliminate the largest fraction of cases of arteriosclerosis is best explained on this hypothesis. The defense of the organism against bacteria is a matter of leucocytosis and diapedesis, which latter also demands an increase in the force of the circulation. On the other hand, hypotension, or a diminution in the force of the circulation, does not appear to serve any useful purpose, and usually, indeed, indicates that the organism is no longer able to defend itself.

THE NEGLECT OF CYNOTHERAPY.

THE subject of the extremes of medical specialism has long since been exhausted as a source of facetious comment. Looking at it from one angle, we find a limitation of interest to such circumscribed regions of the body that weighty tomes appear upon diseases of the umbilicus; from another viewpoint we find a single system of therapy claiming its exclusive votaries, as witness the hydrotherapeutists. May we then register a protest at the neglect of an important branch of therapy? We refer, of course, to cynotherapy.

Our medical ancestors recognized and were not slow to recommend this therapeutic agent. Thus Hippocrates suggests dog meat as a remedy for tuberculosis. It appears, too, from a casual glance at a medical treatise by Qádi Abu Ali at-Tanukhi, of the tenth century, that he was not unfamiliar with its virtues. He reports a case where broth made from the flesh was administered to a boy who was suffering from intolerable gastric pain. The actual ingestion had no effect, but when the boy was told what he had taken, the resultant emesis revealed a cattle-tick which had fastened itself to the gastric mucosa and was causing the pain. All of the early pharmacopeias mention this therapeutic agent, the French one of Nicolas Lemery in 1697 describing an oil, a liniment, and an ointment. Some of these are still in use to-day, particularly in the rural districts, where the oil has a steady sale as a sovereign remedy for rheumatism.

We might call attention to another branch of this therapeutic method which has also enjoyed the esteem of the laity for many centuries and which, being dependent upon external application, might well be termed cynoglossotherapy. Cynoglossotherapy was popularly supposed to have a particularly favorable effect in cutaneous disorders, and there are not wanting testimonials recording the cure of several members of a family of such a disease as scabies by this means.

Then, too, the psychic effects produced by the judicious use of cynotherapy must not be overlooked. In depressions of various sorts, those due to financial reverses or those domestic problems which intrigue the psychoanalyst, cynotherapy not infrequently succeeds in raising the morale of the patient and by providing an atmosphere of loyalty and devotion tends to distract his mind from his difficulties. Let us then not neglect cynotherapy, especially in its last-named aspect, always remembering that the physician himself is sometimes the better for it, if not during his active practice, at least in his vacation time when its application is accompanied by outdoor rambles through fields and woods.

"WEICHSELBAUM'S DISEASE."

THE *Revista Medico-Chirurgica do Brazil* of Rio de Janeiro, founded by Carlos Seidl and edited by Carlos Seidl, Jr., contains in its October issue (xxix, 10) an account by Renzo of an epidemic at Rio of "Weichselbaum's disease," which ran its course in 1920. Evidently the author or some one before him has given this name to cerebrospinal meningitis because Weichselbaum happened to discover the meningococcus. This sort of christening, if followed out, would make of typhoid fever "Eberth's disease," of diphtheria "Löffler's disease," and so on. The autonomy of cerebrospinal fever has been recognized for considerably longer than a century—longer, in fact, than that of typhoid fever or diphtheria, for the latter disease did not receive its modern designation until the appearance of Bretonneau's monograph in 1826. Possibly the attempt to tag epidemic meningitis with Weichselbaum's name may be regarded in the light of supersubtle German propaganda, and if this be the case we may expect to see the French come back with "Bretonneau's disease" for diphtheria, "Laennec's disease" for peritonitis, or atrophic cirrhosis of the liver, and so on. If diseases are to be named for the discoverers of their specific causes syphilis will have to be renamed for Schaudinn, tuberculosis for Koch, leprosy for Hansen, and gonorrhea for Neisser. The tendency in question has cropped out before, when one author speaks of typhoid fever as "eberthian sepsis," and another of gonorrhea as a "neisserian infection." Dr. Renzo, however, anticipates criticism for his novel title, first by passing the buck to Dr. Garfield de Almeida, and second by the statement that since cerebrospinal meningitis is not necessarily epidemic the name in use is not suitable for characterizing the sporadic case. But no one ever thought of calling a sporadic case anything but sporadic cerebrospinal meningitis.

SIMULATION OF A NEOPLASM BY SYPHILITIC ORCHITIS.

IT is not often that a medical writer goes back forty years for an illustrative case, save perhaps an an indication of the medical teaching of the period. The simulation mentioned could hardly have been possible to-day. Nevertheless, Zeissl of Vienna (*Wiener klin. Wochenschrift*, Dec 1, 1921, xxxiv, 48) finds this old case of unusual teaching value. The patient, a young physician, had acquired two years before one of those very doubtful cases of syphilis which puzzle the medical advisers. Practically aside from a hard chancre there was no evidence of syphilis whatever—no cutaneous or mucous lesions, loss of hair, or disturbance of general health. A left hydrocele then suddenly developed, and after puncture no lesion of the testicle, epididymis, or cord could be palpated. At this juncture there developed a lymphnode enlargement in the left epitrochlear region the size of a pigeon's egg. The patient became panic-stricken, having made the diagnosis of carcinoma of the testicle with lymphnode metastases, and demanded semicastration and extirpation of the enlarged node. The author cut down on the testicle and evacuated a little pus, making also a biopsy of a piece of the gonad. The diagnosis of the pathologist was an inflammatory process of syphilitic nature. The testicle became normal and the operation wound healed under an inunction and iodide cure. The enlarged node subsided. There had been a slight rise of temperature and pain in the gonad, which also disappeared. The case is singular, therefore, for pain and fever seldom accompany syphilitic or-

chitis. The testicle may reach the size of a pear and the condition usually persists for months uninfluenced by treatment. Careful palpation shows that the enlargement is nodular. The author briefly outlines the differential diagnosis of gonorrheal epididymitis, syphilitic orchitis, tuberculosis, and cancer of the testicle.

News of the Week.

Influenza in Great Britain.—A large increase in the death rate in Great Britain during the first week in January is reported by the Registrar General to be due largely to influenza. In London the deaths from this cause were 354, as compared with 151 in the previous week. In 105 towns of England and Wales the deaths from influenza numbered 819.

Births and Marriages Decrease in France.—According to the report of the Ministry of Labor, marriages in France decreased about 30 per cent. during the last year. Whereas in 1920 there were 333,242 marriages, there were in 1921 only 238,185. Births showed a decrease of 3,483, but this was offset by a decrease of deaths of 8,400.

Tuberculosis in the United States.—The Department of Commerce announces that nearly 100,000 deaths were due to tuberculosis in the death registration area of the United States in 1920, and if the rest of the United States has as many deaths from this cause in proportion to the population, the total number of deaths from tuberculosis in the entire United States for 1920 was about 122,000 while, for 1919 the number is estimated as 132,000, or 10,000 more than for 1920. The tuberculosis death rate in the registration area in 1920 was 114.2 per 100,000 population against 125.6 per 100,000 population for the year 1919.

Smallpox Outbreak in Oklahoma Towns.—An epidemic of smallpox is reported from the towns of Poleau, Heavener and Wister, Okla. These towns have been isolated by barbed wire entanglements and are guarded by armed men. Compulsory vaccination is being enforced. To January 13, ten deaths from the disease had occurred in Poleau.

Appropriation to Fight Scarlet Fever in New York.—The Board of Estimate has granted the Health Commissioner an appropriation of $75,000 to employ additional physicians, nurses, and inspectors in connection with an unusual number of scarlet fever cases in the city and to take precautions against the possible recurrence of an epidemic of infantile paralysis, which usually runs in cycles of five or six years. In 1920 there were 6,885 cases of scarlet fever here, and 13,880 in 1921. A part of the appropriation will be spent for laboratory study of scarlet fever and infantile paralysis.

Extension of Prenatal Work.—The Maternity Center Association of New York City is cooperating with the Department of Health in extending its prenatal service in the Borough of Manhattan. The Association will furnish doctors and nurses to hold clinics for expectant mothers in certain Baby Health Stations maintained by the Department, and the doctors and nurses attached to the Baby Health Stations will cooperate in the maintenance of these prenatal clinics. As a sufficiently large appropriation to extend the prenatal service of the Bureau of Child Hygiene is not at present available, the Department of Health welcomes the cooperation of organizations who are working to reduce the maternal and early infant death rates by furnishing instruction to expectant mothers.

Males and Females.—A bill has been introduced into the New York Legislature forbidding a male doctor to treat a female except in the presence of another female. The bill was introduced by Mr. Male. It is one of the comic reliefs of the popular legislative meddling in medical matters.

Association of the Alumni of the College of Physicians and Surgeons.—The annual meeting of this Association will be held on Tuesday, January 24, 1922. Dinner will be served at 7 o'clock at the Faculty Club, Columbia University, Broadway and 116th Street. At 8.45 o'clock the executive session will be called to order at the Crocker Laboratory, 1145 Amsterdam Avenue, northeast corner of 116th Street. At 9 o'clock Professor Francis Carter Wood will demonstrate the new high voltage *x*-ray apparatus at the Crocker Laboratory and will talk on some of the recent developments in *x*-ray therapy. The secretary of the Association is Dr. William H. Woglom.

New York Medical Association.—The annual meeting of this association was held on January 12 at the Sherman Square Hotel. The business of the meeting consisted of a report of the work done by the association since its formation in 1919, the election of officers for the ensuing year, and the passage of resolutions on pending matters of legislation affecting the medical profession. Dr. Theodore Knapp Tuthill was elected President; Dr. S. Irwin Nelson, Vice-president, and Dr. John P. Davin, Executive Secretary. The Congressional investigation of the Narcotic Drug Situation as proposed by Representative Lester D. Volk was approved. The proposed suit by the New York Medical Association to test the constitutionality of the so-called Anti-Beer Bill was also approved. The bill introduced in the New York Legislature making it compulsory for a male physician to have a woman present while examining a woman patient was disapproved unless this bill should be amended so as to work also the other way round.

Address by Dr. Pirquet.—The stated meeting of the Section on Pediatrics of the New York Academy of Medicine of January 12 was held in conjunction with the New York Nutrition Council, the American Relief Administration, and the Health Service of the New York Chapter of the American Red Cross. Dr. Clemens Pirquet of Vienna delivered an address on his now familiar standards of child nutrition, which was illustrated with lantern slides showing how the American relief work was being conducted in Vienna.

Dr. B. P. Battalore, formerly connected with the Gulfport Naval Hospital, has resigned from the naval service and will practise medicine in New Orleans.

Dr. William Seaman Bainbridge, Commander M.C., U.S.N.R.F., has been decorated by the French

Government with the officer's cross of the Legion of Honor in recognition of his work with the allied armies at the various fronts and in the preparation of a "Report on the Medical and Surgical Developments of the War."

Dr. A. G. Ireland, associate professor of hygiene and public health at the University of Kentucky, has been appointed to the position of state supervisor of physical education and health by the Connecticut State Board of Education.

Dr. W. O. Bullock has been reelected president of the Board of Health of Lexington, Ky.

Dr. George H. Reichers has been elected president of the governing board and president of the staff of the Bushwick Hospital, Brooklyn, N. Y.

Dr. Maurice J. Lewi was the guest of honor at a dinner given at the Hotel Astor on January 14, by his fellow workers in the New York Heath Department. The Health Commissioner was toastmaster.

Colonel George E. Bushnell, M.C., U. S.A., Retired, who is to be in charge of the new military unit in Harvard Medical School, has been appointed Professor of Military Science and Tactics.

Dr. William J. Robinson and Dr. Martin Rehling were reelected President and Secretary respectively of the Medical Board of the Bronx Hospital at its annual meeting held Jan. 12, 1922.

Dr. Julius O. Cobb, surgeon in command of Fox Hill Hospital, Staten Island, and the Polyclinic Hospital, Manhattan, has been transferred to Boston to take charge of the United States Marine Hospital there.

A Medical History Society.—An International Society of the History of Medicine has just been established, according to a Paris newspaper, growing out of conventions held at Antwerp in 1920 and at Paris in 1921. The officers are: President, Dr. Tricot Royer, Antwerp; Vice-presidents, Professors Giordano of Venice, Singer of Oxford, and Jeanselma and Ménétrier of Paris; Secretary-General, Professor Laignel-Lavastine of Paris. A convention will be held at London in July, 1922, under the chairmanship of Professor Singer.

Positions for Specialists in Child Hygiene. — The United States Civil Service Commission announces an open competitive examination for specialists in child hygiene, to fill vacancies in the Children's Bureau, Department of Labor, Washington, D. C., at $2,400 to $4,000 a year, and vacancies in positions requiring similar qualifications. Applicants should apply for Form 2118, stating the character of the examination desired to the Civil Service Commission, Washington, D. C., or to the secretary of the local board of civil service examiners at the post office or custom house in any city. The receipt of applications closes February 14, 1922.

Automobile Deaths in 1921.—At a joint meeting of the officers of the Public Safety Section of the National Safety Council and the managers of various local safety councils, held in Chicago January 13, it was estimated that the number of persons killed in automobile accidents in the United States in 1921 was between 12,000 and 15,000, probably nearer the higher figure. This is an increase of from 1000 to 4000 over deaths from automobile accidents in 1920, when approximately 11,000 persons were killed. Based on the higher figure, safety officials to-day said that death from an automobile accident in 1921 occurred on an average of every thirty-five minutes.

Hospital Notes. — Plans for establishing a $500,000 hospital in Newark for the exclusive treatment of cripples, under the supervision of Dr. Adolf Lorenz, are being considered by city officials and members of the medical profession as the result of a pledge made by one of the city's foremost citizens to donate $100,000 and real estate valued at $50,000 for the project. The philanthropist, whose name is withheld, has made the offer on condition that if the institution is established it shall bear his family name.

The Seaside Home for Crippled Children at Far Rockaway, N. Y., recently celebrated its tenth anniversary at a meeting in the Biltmore Hotel, New York. Addresses were made by Lieutenant Governor Jeremiah Wood and Dr. Virgil P. Gibney.

The American Legion Weekly announces that the American Legion posts of Minnesota expect to erect a $200,000 hospital for the treatment of soldiers of the World War, and that Drs. William and Charles Mayo will cooperate in the work of the institution. Patients will be charged fees according to their ability to pay, as determined by the Legion officials.

Plans are being worked out for the erection of two new wings to the Mercy Hospital at Oshkosh, Wis., at a cost of about $300,000. Work will probably be begun in the spring and when the building is completed it will be used as a general hospital instead of simply as a maternity hospital as heretofore.

The Hudson City (N. Y.) Hospital has been fully completed and was formally opened on December 30, 1921.

Physicians' and Surgeons' Hospital Board of Kansas City, Mo., plan to erect a new hospital building to replace the one now operating at Eleventh and Harrison Streets. An effort will be made to conduct the new institution on the "open staff" method.

Mayor Couzens of Detroit has given $1,000,000 for the purpose of consolidating the Children's Free Hospital and the Michigan Hospital at Framington to provide additional facilities for the treatment of crippled children in Michigan. Additional contributions to the amount of $5,000,000 will be made as fast as the money is needed for the development of the joint hospital.

An Inquiry Regarding the Latest Interpretation of the Harrison Law.—Representative Volk of New York has introduced the following resolution, calling for facts in the possession of the Secretary of the Treasury regarding the authority for certain restrictions on medical practice promulgated recently by the prohibition commissioner:

Resolved, That the Secretary of the Treasury be, and he is hereby, authorized to transmit to the House of Representatives the facts in his possession on which, under date of October 19, 1921, R. A. Haynes, prohibition commissioner, did cause to be set forth and publish a ruling or regulation outlining treatment of "narcotic drug addiction" permissible under the Harrison law, and under section b of the aforesaid rules and regulations entitled "The ordinary addict," stated: "It is well established that the ordinary case of addiction yields to proper treatment and that addicts will remain

permanently cured when drug taking is stopped and they are otherwise physically restored to health and strengthened in will power. This bureau has never sanctioned or approved the so-called reductive ambulatory treatment of addiction, however, for the reason that where the addict controls the dosage, he will not be benefited or cured. Medical authorities agree that the treatment of addiction with the view to effecting a cure, which makes no provision for confinement while the drug is being withdrawn, is a failure, except in a relatively small number of cases where the addict is possessed of a much greater degree of will power than that of the ordinary addict. The good faith of the physician and the bona fides of his treatment in a given case will be established by the facts and circumstances of the case and the consensus of medical opinion in regard thereto, based on the experience of the medical profession in cases of a similar nature.

"The following resolution passed by the Council on Health and Public Education of the American Medical Association, at the meeting on November 11, 1920, is pertinent in determining the period over which narcotic treatment should be extended in purely addiction cases: '*Be it resolved*, That the Council on Health and Public Education of the American Medical Association indorse the principle expressed in the California law (section 8½), which forbids the use of opium and its derivatives in the withdrawal treatment of those addicted to the use of these drugs for a period of more than thirty days after the commencement of the withdrawal treatment.'

"This bureau cannot under any circumstances sanction the treatment of mere addiction where the drugs are placed in the addict's possession, nor can it sanction the use of narcotics to cover a period in excess of thirty days, when personally administered by a physician to a patient neither in a proper institution nor unconfined. If a physician, pursuant to the so-called reductive ambulatory treatment, places narcotic drugs in the possession of the addict who is not confined, such action will be regarded as showing lack of good faith in the treatment of the addiction, and that the drugs were furnished to satisfy the cravings of the addict. Doubtful cases, or those not falling within any of the above instructions, upon request will be investigated and special instructions, based upon the recommendations of the inspecting officers, will be issued."

Resolved further, That the Secretary of the Treasury is also hereby directed to inform the House as to the facts (1) on which a curb is placed upon the professional judgment of the doctor treating addiction, (2) which necessitate the direction of medication by the prohibition commissioner or his inspectors, (3) which show the qualifications of the prohibition commissioner or his inspectors charged with this work to pass upon medical treatment of narcotic drug addiction; their association with or knowledge of addiction treatment; or their qualifications as either physicians, dentists, or veterinarians, or their training in the science of medicine or its branches, such as therapeutics, pathology, or as laboratory specialists, blood analysts, clinicians, or as general practitioners, which would enable them to qualify to pass judgment upon cases of narcotic addiction or issue special instructions with regard to the treatment thereof.

Resolved further, That the Secretary of the Treasury is also hereby directed to inform the House as to the facts concerning the existence of any statute under and by virtue of which the Secretary of the Treasury, or, through him, the Federal Prohibition Commissioner by rules and regulations, is empowered to set aside known facts in medical science and curb the legitimate practice of medicine; and to nullify an Act of Congress, to wit, the Harrison narcotic law, passed in 1914, and which as revised and amended sets forth in section 1, as follows: "That the provisions of this paragraph shall not apply . . . to the dispensing, or administration, or giving away of any of the aforementioned drugs (opium derivatives) to a patient by a registered physician, dentist, veterinarian, or other practitioner in the course of his professional practice, and where said drugs are dispensed or administered to the patient for legitimate medical purposes, and the record kept as required by this Act of the drugs so dispensed, administered, or given away."

Resolved further, That the Secretary of the Treasury is also hereby directed to inform the House as to the facts which necessitate denying to the narcotic addict the advice and treatment of his family physician, and which under the rules and regulations as issued seek to force him to accept the treatment provided by penal institutions, private sanitariums, and quack "drug-cure" proprietors.

Resolved further, That the Secretary of the Treasury is also hereby directed to correlate and inform the House the facts or addenda covering the following interrogations: (1) The names or name of the official of the Internal Revenue Department writing section b of the regulations promulgated October 19, 1921. (2) The qualifications of this person or persons to pass upon the medical treatment or narcotic drug addiction, his association with and knowledge of addiction treatment. (3) The name or names of the Council on Health and Public Education of the American Medical Association adopting the resolution prescribing thirty days as the length of time which shall not be exceeded in treating addiction by the administration of narcotics. (4) The status of that resolution in the main body of the American Medical Association setting forth the adoption or rejection of the aforesaid resolution by the American Medical Association in convention assembled. (5) The medical authorities upon which reliance is placed for the quoted statement in paragraph 2, section b, of the rules and regulations. (6) Any and all additional facts relating to the rules and regulations, together with any information bearing upon the subject matter of this resolution.

Campaign for Law Requiring National License to Practise Medicine.—A movement to have Congress pass a law requiring all graduates in medicine to take out a national license to avoid the complex requirements of the different States and to facilitate medical practice was inaugurated at a meeting of the officials and counsellors of the American College of Physicians held in Philadelphia on December 30, 1921. Dr. Ellsworth Smith of St. Louis presided at the meeting. Dr. Clement R. Jones of Pittsburgh, who detailed the disadvantages of the present system, suggested that licenses be taken out through a national department of health or other Federal division.

Gifts and Bequests.—By the will of the late Frank Bringhurst of Philadelphia bequests are made as follows: Children's Seashore Home at Atlantic City and the North American Sanitarium at Atlantic City, each $10,000; Home for Incurables, Lankenau Hospital and Episcopal Hospital, each $5,000; Germantown Hospital, $1,000.

By the will of the late Ernest L. Tustin of Philadelphia one-quarter of the residue of an estate of about $500,000 is bequeathed to Hahenamann Hospital and Medical College of Pennsylvania for the purpose of supporting beds in the name of Ernest L. and Ellen W. Tustin for the benefit of poor and destitute children.

A legacy of $5000 is bequeathed to St. Joseph's Hospital, Philadelphia, by the will of the late Catherine Buckbee, for the endowment of a free bed in memory of her mother, Catherine Riley.

George P. Mellick and John H. Stevens have each made a donation of $25,000 to the Muhlenberg Hospital at Plainfield, N. J., for the construction of an extension to the Nurses' Home.

Medical Society Elections.—The Bastrop County Medical Society, at its regular meeting held in Bastrop, Texas, Dec. 15, 1921, elected as officers for the ensuing year: *President*, Dr. W. E. Campbell, Elgin; *Vice-President*, Dr. P. Chapman, Smithville; *Secretary and Treasurer*, Dr. I. J. Dawson.

THE PALM BEACH MEDICAL SOCIETY, at its regular meeting held at West Palm Beach, Fla., Dec. 13, 1921, elected the following officers for the ensuing years: *President*, Dr. R. O. Cooley; *Vice-President*, Dr. C. M. Conkling; *Secretary and Treasurer*, Dr. Grace Papot, Lake Worth.

THE SONOMA COUNTY MEDICAL SOCIETY, at its regular meeting held in Healdsburg, Cal., Dec. 15, 1921, elected the following officers for the ensuing year: *President*, Dr. L. J. Wilson, Sebastopol; *Vice-President*, Dr. H. S. Rogers, Petaluma; *Secretary*, Dr. L. W. Juell, Santa Rosa; *Treasurer*, Dr. W. C. Shipley, Cloverdale.

THE SOUTHSIDE MEDICAL SOCIETY, at its regular meeting held in Petersburg, Va., Dec. 20, 1921, elected the following officers for the ensuing year: *President*, Dr. T. M. Raines, Wakefield; *Vice-President*, Dr. W. C. Harmon, Dolphin; *Second Vice-President*, Dr. W. C. Powell, Petersburg; *Third Vice-President*, Dr. W. T. Gay, Suffolk; *Fourth Vice-President*, Dr. E. F. Reese, Courtland; *Secretary and Treasurer*, Dr. R. L. Ralford, Sedley.

THE MEDICAL SOCIETY OF THE COUNTY OF MONTGOMERY, at its regular meeting held in Amsterdam, N. Y., Dec. 15, elected the following officers for the ensuing year: *President*, Dr. R. R. Canna, Amsterdam; *Vice-President*, Dr. Harry H. Howard, Minaville; *Secretary*, Dr. W. R. Pierce, Amsterdam; *Treasurer*, Dr. C. F. Timmerman, Amsterdam.

THE SYRACUSE ACADEMY OF MEDICINE, at its annual meeting held Dec. 20, 1921, elected the following officers for the ensuing year: *President*, Dr. Charles Post; *Vice-President*, Dr. Edward Reifenstein; *Secretary*, Dr. C. J. Geiger; *Treasurer*, Dr. C. W. Blodgett.

THE DINWIDDIE COUNTY MEDICAL SOCIETY, at its annual meeting held in Petersburg, Dec. 15, 1921, elected the following officers for the ensuing year: *President*, Dr. R. A. Martin; *Vice-President*, Dr. E. W. Perkins; *Secretary-Treasurer*, Dr. William C. Powell.

THE FRANKLIN COUNTY MEDICAL SOCIETY, at its annual meeting held in Ozark, Ark., Dec. 15, 1921, elected the following officers for the ensuing year: *President*, Dr. A. J. Hansberry; *Vice-President*, Dr. E. W. Black; *Secretary*, Dr. Thomas Douglass.

THE SANDUSKY COUNTY MEDICAL SOCIETY, at its annual meeting held in Freemont, Ohio, Dec. 24, 1921, elected the following officers for the ensuing year: *President*, Dr. M. O. Phillips; *Vice-President*, Dr. R. D. Reynolds, Greenspring; *Treasurer*, Dr. W. H. Booth; *Secretary*, Dr. C. I. Kuntz.

THE MEDICAL SOCIETY OF THE COUNTY OF ERIE, at its annual meeting held in Buffalo, N. Y., Dec. 20, 1921, elected the following officers for the ensuing year: *President*, Dr. Dewitt H. Sherman; *Vice-President*, Dr. Thomas J. Walsh; *Second Vice-President*, Dr. Edgar R. McGuire; *Secretary*, Dr. Franklin C. Gram; *Treasurer*, Dr. Albert T. Lytle; *Censors*, Dr. John D. Bonnar, Dr. Charles W. Bethune, Dr. Archibald D. Carpenter, Dr. Francis E. Fronczak, Dr. Frank A. Valente.

THE CALHOUN COUNTY MEDICAL SOCIETY, at its annual meeting held in Battle Creek, Mich., Dec. 6, 1921, elected the following officers for the ensuing year: *President*, Dr. M. A. Mortensen; *Vice-President*, Dr. Thomas Zelinsky; *Secretary-Treasurer*, Dr. Wilfred Haughey.

THE ALBANY COUNTY MEDICAL SOCIETY, at its annual meeting held in Albany, N. Y., Dec. 7, 1921, elected the following officers for the ensuing year: *President*, Dr. T. W. Jenkins; *Vice-President*, Dr. Nelson F. Fromm; *Secretary*, Dr. Emmanuel M. Freund; *Treasurer*, Dr. John E. Heslin.

THE HERKIMER COUNTY MEDICAL SOCIETY, at its annual meeting held in Herkimer, N. Y., Dec. 6, 1921, elected the following officers for the ensuing year: *President*, Dr. Harry W. Vickers; *First Vice-President*, Morris H. Newton; *Second Vice-President*, Herbert T. Crough; *Third Vice-President*, Fred M. Barney; *Secretary*, A. Walter Suiter; *Treasurer*, George Graves.

THE MEDICAL ASSOCIATION OF THE SOUTHWEST, at its annual meeting held in Kansas City, Mo., Oct. 24-28, 1921, elected the following officers for the ensuing year: *President*, Dr. St. Cloud Cooper, Ft. Smith, Ark.; *Vice-Presidents*, Dr. G. Wilse Robinson, Kansas City; Dr. A. F. O'Donnell, Ellsworth, Kan.; Dr. C. R. Day, Oklahoma City, and Dr. T. C. Terrell, Fort Worth.

THE MISSOURI VALLEY MEDICAL SOCIETY, which held its annual meeting in conjunction with the Medical Association of the Southwest at Kansas City, Mo., Oct. 24-28, 1921, elected the following officers for the ensuing year: *President*, Dr. Paul E. Gardner, New Hampton, Ia.; *First Vice-President*, Dr. H. J. Lehnhoff, Lincoln, Neb.; *Second Vice-President*, Dr. Austin McMichael, Rockport, Mo.; *Treasurer*, Dr. O. C. Gebhart, St. Joseph, Mo. (re-elected); *Secretary*, Dr. Charles Wood Fassett, Kansas City, Mo. (re-elected).

THE MID-WEST ASSOCIATION OF ANESTHETISTS, at its annual meeting held in Kansas City, Mo., Oct. 24-28, 1921, elected the following officers for the ensuing year: *President*, Dr. David E. Hoag, Pueblo, Colo.; *First Vice-President*, Dr. B. H. Harms, Omaha, Neb.; *Second Vice-President*, Dr. Winnie M. Sanger, Oklahoma City; *Secretary*, Dr. Morris H. Clark, Kansas City.

THE MAUMEE (TOLEDO) MEDICAL SOCIETY, at its annual meeting held Dec. 8, 1921, elected the following officers for the ensuing year: *President*, Dr. J. D. Ely; *Vice-President*, Dr. Sara Davies; *Secretary*, Dr. James C. Price; *Treasurer*, Dr. George Beyer.

THE AMERICAN SOCIAL HYGIENE ASSOCIATION, at its eighth annual meeting held in New York City, Nov. 18, 1921, elected the following officers for the ensuing year: *President*, Dr. Hermann M. Biggs, State Health Commissioner of New York; *Vice-Presidents*, Dr. William S. Keller, Cincinnati, and Dr. John H. Stokes, Rochester, Minn.

THE SULLIVAN, CARTER AND JOHNSON COUNTIES (VA.) MEDICAL SOCIETY, at its meeting held in Bristol, Dec. 3, 1921, elected the following officers for the ensuing year: *President*, Dr. J. O. Woods, Elizabethton; *Vice-Presidents*, Dr. B. A. Swift, Mountain City; Dr. C. C. Hacker, Elizabethton; Dr. W. R. Booher, Bristol; *Secretary and Treasurer*, Dr. W. K. Vance, Jr.

THE NEW YORK STATE SOCIETY OF INDUSTRIAL MEDICINE, at its first annual meeting held in Syracuse, Dec. 8, 1921, elected the following officers for the ensuing year: *President*, Dr. T. G. Smith, Schenectady; *First Vice-President*, Dr. C. H. Weston, New York City; *Second Vice-President*, Dr.

R. W. Chaffee, Syracuse; *Secretary*, Dr. Myer Bloom, Binghamton; *Treasurer*, Dr. S. M. Slater, Rochester.

Obituary Notes.—Dr. J. WILLIAM PANCOAST, a graduate of Pennsylvania University School of Medicine in 1892, died suddenly of heart disease at his home in Philadelphia on January 3, at the age of fifty-two years. He was a member of the American Medical Association and of the Medical Society of the County of Philadelphia.

Dr. HERBERT LEE CONSTABLE of New York, a graduate of New York University Medical College in 1889, died of heart disease on December 18, at the age of fifty-five years.

Dr. DAVID LAWRENCE SMITH died at his home in Spokane, Wash., on December 20, at the age of seventy-two years. He was graduated from the Central Medical College of St. Joseph, Mo., in 1892. At different times he was both city health officer and coroner.

Dr. JULIA T. H. CRAWFORD of York, Pa., a graduate of Hahnemann Medical College and Hospital, Chicago, in 1884, and of the Women's Medical College of Baltimore in 1886, died in a Los Angeles hospital on December 24, at the age of sixty years.

Dr. FREDERICK H. DAVIS of Darby, N. J., a graduate of Jefferson Medical College in 1891, died on December 21, at the age of fifty-six years.

Dr. HARRY HALE FORD of Elmira, N. Y., a graduate of Bowdoin Medical College in 1884, died on December 25, at the age of fifty-eight years. He was a member of the American Medical Association and of the Medical Society of the State of New York, and for more than twenty years consulting physician of the Pennsylvania Railroad for his district.

Dr. OSCAR G. OLSON of Chicago, a graduate of the Kentucky School of Medicine in 1893, died of angina pectoris at his home in Chicago on December 26, at the age of fifty-seven years.

Dr. SAMUEL C. FALLS, a graduate of the Medico-Chirurgical College, Philadelphia, in 1893, died suddenly at his home in Philadelphia on December 26, at the age of fifty years. He served in the Medical Corps of the Army during the war with the rank of major.

Dr. THOMAS J. WHITNEY of Frewsburg, N. Y., a graduate of the University of Buffalo Medical College in 1865, and a Civil War veteran, died on December 24, at the age of seventy-nine years.

Service Bureau.

Regular subscribers to the MEDICAL RECORD who desire information on any professional matter are invited to send their inquiries to the office of publication. Replies will be sent by mail as promptly as possible. Questions and answers of general interest may be published from time to time. When abstracts of articles from other journals are furnished the cost of typewriting will be charged.

Purchases will be made of articles of any description wanted by subscribers; a check sufficient to cover the cost should be sent with the order.

Subscribers visiting New York are welcome to use the office, 51 Fifth Avenue, as a temporary address for receiving and forwarding mail, telegrams, or small packages.

Correspondence.

A CALL FOR REFORM IN THE AMERICAN MEDICAL ASSOCIATION.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—As the fate of the Practice of Medicine is at stake, the following is being sent to every Medical Editor and County Medical Society in the United States. Kindly submit it to the readers of your journal for consideration and action.

F. H. McMECHAN, M.D.,
Secretary.

To Members of the Medical Profession: The public and professions are being sold out to (1) foundation control of "full time" medical education; (2) lay board domination and the "closed shop" hospital; (3) socialized State medicine, subsidized community health centers, and hospitals under political or university control; (4) legislative dictation of therapy and fees; (5) demoralization of medical standards by the expansion of cults; (6) exploitation of the specialties by lay technicians. These menacing movements will succeed unless they are combated by a powerful and united opposition. Your so called leaders are either openly fostering these destructive forces, or more subtly giving them full fling by a camouflaged neutrality.

The American Medical Association belongs to you and you are entitled to have it effectively protect your vital interests. Let your action on this nationwide referendum carry your mandate. In the present crisis it is up to every county society to instruct all delegates to the A. M. A. meeting at St. Louis, Mo., May 22-26, 1922, to vote for (a) a change of policy and leadership in the A. M. A. pledged to the immediate abolition of the evils mentioned, and constructive protection of medical interests; (b) the repeal of multiple representation and plural voting privilege by section delegates; (c) the election of trustees for a period of two years, five trustees to be elected one year and four the next, to prevent the trustees from perpetuating oligarchical rule. Unless there is a drastic change in the policy and leadership of the A. M. A. the public and profession at large will continue to be misled and misrepresented in the solution of the most pressing problems affecting public welfare and the practice of medicine.

The members of the scientific sections are already represented by the delegates of their respective State societies, and the voting of section delegates is multiple representation, and as such undemocratic and unfair. Unless this plural voting privilege is repealed, the fifteen section delegates will continue to negative and outvote the delegates of fifteen State societies having only one delegate each.

At present three of the nine A. M. A. trustees are elected each year for a period of three years. There is a proposal before the House of Delegates, introduced at the Boston meeting (1921), to reduce the number of trustees to seven and have the term of office seven years. Unless the proposed election of trustees for seven years is nipped in the bud, the A. M. A. will be relegated to "gang rule" for all time to come.

At the Boston meeting of the A. M. A. (1921), those representing the rank and file of the profession lacked only seven votes of being in control of the House of Delegates, and would have been able to initiate a policy of public and medical protection if they had not been outvoted by the section delegates. In this connection the following editorial note or warning is of pertinent interest:

..."For the benefit of the large number of State journals that exchange with us, we desire to call attention to the necessity of determining where the delegates to the A. M. A. stand on many questions of vital interest to the welfare of the medical profession at large. We have had examples of what some of the leaders in the profession would do to us if they have their way. It is time to know something about the attitude of those whom we send to represent us at the great parent organization, which supposedly represents the voice of a very large majority of the medical men in this country. The trouble of it is we sometimes are betrayed, and if necessary, in order to have our wishes respected, our delegates ought to go instructed."—*Jour. Indiana State Medical Society*, November, 1921.

This warning is all the more necessary since the board of trustees, at the Boston meeting (1921), reported that they had under consideration the advisability of the A. M. A. paying the expenses of the A. M. A. delegates. This simply means further subsidizing of the delegates to control their votes and to thwart the interests of the rank and file. Each State society that values representation by its own delegates must take action against this political maneuver.

This is your opportunity of putting your power of attorney into the keeping of only such delegates to the St. Louis meeting who will openly avow their stand on all vital matters, who will fight your battles, and to whom your interests will be a sacred trust. Self-protection is the first law of life. Act now!

MEDICAL ADVISORY COMMITTEE.

MERCURIAL TEST FOR SYPHILIS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Criticism without suggested improvement means ignorance or jealousy. But I do not intend to criticise, I simply want to commend Dr. Chester Titus Stone for bringing out some truths regarding a method that has probably done more damage than syphilis has ever dreamed of. How many individuals have been charged with syphilis; been slowly poisoned with arsenical preparations and even mercury, that have never had that disease? Although the conclusions of the Pan American Congress of Genito-Urinary men in Washington, D. C., in December, 1920, declared the Wassermann to be of practically no value, unless accompanied by clinical evidences, past or present, we yet find men having Wassermann tests taken for every pain or ache.

My personal experience with the Wassermann is in two cases. One an initial lesion, that had I waited a few days would have shown the true condition; the test was reported as positive. The second (I tried this just as an experiment) was the case of a woman whom I had had under treatment for from five to eight months. To be fair with the test, I did not give any mercury for two weeks previous to the test, nor did I allow her to touch alcoholic beverages. A report was returned as negative. Simply smiling, I continued her treatment for three years; occasionally a symptom would develop during this time. The woman was treated for three years with mercury; she is now perfectly well five years afterward.

I wish to offer a method that is as sure as any Wassermann, to me more so; one that any one can carry out in a few seconds, and positively prove in the course of two to four days. It is well known that mercury acts as a specific in syphilis, and it must be evident to any one who has used it, that if this disease is not present, the administration of the drug, even in the smallest dose, is invariably accompanied by the physiological symptoms of mercury. On the other hand, if syphilis is present, one can take doses that would kill an ordinary person free from the disease. The following briefly reported cases must show the truth of the above claim:

J. Y. Ulcer at frenum. Infection, if such, was very indefinite, there being three sexual contacts inside of four weeks. The blue halo, to the writer a positive point in the diagnosis of specific ulcer, was present, but no other evidences of the disease. One-eighth grain of mercury bichloride was given hypodermically (mercury bichloride, 5 gr., beta eucaine 2½ gr., water one ounce; 24 drops equals ¼ gr. mercury). Returning in 24 hours he complained of no bad symptoms whatever as a result of the injection. One-fourth grain was now given, with advice to return in 48 hours. The same report: no bad symptoms. The ulcer, which at the first visit was covered with a slimy grayish substance, now appeared red (new granulations) and epithelium was springing from all sides in an effort to close it over; this was complete in a week's time. There was no doubt of the diagnosis. About the sixth week he developed a few mucous patches and slight eruption.

T. K. Sent by the same patient with a similar sore, only slightly higher up. There being no blue halo, the condition was shown to a specialist on the skin who pronounced it as specific and advised treatment at once. One-eighth grain mercury bichloride was given hypodermically. In 48 hours he reported: "Three hours after the injection, cramps, diarrhea, spitting constantly, and slight tenderness of the teeth." This should have been sufficient, but in view of the opinion of the expert, a second injection of 1/6 grain was given. In 48 hours he reported: "Diarrhea with blood, severe cramps, mouth full of saliva constantly, runs all over the pillow at night; the gums were badly swollen." This was convincing that a mistake had been made, and the ulcer was cleansed with iodine water and dressed with iodoform. In a week he reported with sore practically closed over, and no other symptoms.

The writer has used this method scores of times, even where the infection was of years' standing; where syphilis is present, physiological symptoms never develop; where it is absent, always.

J. HENRY DOWD, M.D.

BUFFALO, N. Y.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, January 3, 1922.

Medical Men in Parliament.—It is curious, to some extent, to observe the ignorance of the members of the medical profession in this country as to its representation in Parliament and also the proposed contempt the average medical man has for politics. He believes, if he thinks of the matter at all, that politics will effect nothing in his interests, that indeed they are antagonistic to his concerns, as, in fact, they usually seem to be. However, there is a medical group in the British House of Commons, small though it be and comparatively negligible as its influence is. The existing British Parliament contains eleven medical members whose names and politics are as follows: Dr. Addison, late Minister of Health, Liberal; Sir William Watson Cheyne, Unionist; Captain W. E. Elliott, Unionist; Dr. A. C. Farquarson, Liberal; Lieut.-Colonel F. E. Freemantle, Unionist; Dr. B. F. P. McDonald, Unionist; Dr. J. E. Molson, Unionist; Mr. Donald Murray, Liberal; Dr. Nathan Raw, Unionist; Sir William Whitla, Unionist; Sir Robert Woods, Independent. Although the medical party is almost impotent politically, it has formed the Medical Committee of the House of Commons which has rendered considerable service to the cause of public health. Some of the members of the medical party have shown themselves remarkably energetic as well as possessed of marked ability as speakers. Perhaps Captain Elliott may be termed the orator of the party, although Dr. Nathan Raw, Lieut.-Colonel Freemantle, and Dr. Murray have distinguished themselves in this direction on several occasions. The Parliamentary Committee is working in conjunction with the Federation of Medical and Al-

lied Societies through its secretary, who has a seat on the Medical Council. Moreover, all the medical members of Parliament, with one exception, also are individually members of the federation. The federation serves the committee in the House and outside the House. It does this by supporting all medical candidates for Parliament by canvassing all members of all the professions allied with the medical profession, and by providing the committee with the views of the medical and kindred societies on current health matters. But, of course, as said before, the number of medical men in Parliament is so small as to carry little if any weight, and it would be in the best interests of the profession and of the health of the country if there were enough medical men and women in Parliament, not only to represent adequately the opinion of the profession as regards health matters, but to look after and, if possible, safeguard their own interests. Unfortunately, the calls of medical practice are so exacting that there are not many who have the leisure and what is more to the point, the means to contest a parliamentary election, or if elected to support themselves. Unfortunately, too, in any event, the number of men in Parliament would not be sufficient to make their influence felt as it should be felt. Politicians, many of whom may be termed professional politicians, possess the power, and the medical profession must either sing to their tune or go unheeded. In no countries of the world is the medical profession so politically powerless as in this country and America.

British Medical Association.—The next annual meeting of this Association will be held in Glasgow in July. It is stated that the committees in charge of the various departments are now well under way, and the preparations for the coming meeting are already in a forward condition. A short time ago the Central Arrangements Committee held its first meeting in London, but the detailed discussion of the work and office-bearers of the scientific sections has been postponed until the next meeting. Among other arrangements made was the decision to publish a series of articles on Glasgow and neighborhood in the *British Medical Journal*, which will appear at monthly intervals. As a matter of fact, the first of this series appeared in the first number of December last.

Health Congress.—The Royal Institute of Public Health will hold a Congress in Plymouth from May 31 to June 5, 1922. In addition to conferences on various matters there will be four sections: (1) State Medicine and Municipal Hygiene; (2) Naval, Military, and Air; (3) Bacteriology and Bio-Chemistry; (4) Women and Public Health. The Harben Lectures will be given during the meeting by Dr. T. Madsen, director of the State Serum Institute, Copenhagen. A course of lectures on Tuberculosis and Public Health will be given in the lecture hall of the Institute on Wednesdays, January 11 to March 22, 1922, at 4 P. M.

Third International Congress of the History of Medicine.—At a general meeting held at the Royal Society of Medicine on December 21, 1921, the following were elected officers of the Congress: President of Honor, Sir Norman Moore; President, Dr. Charles Singer; Treasurer, Mr. W. G. Spencer; General Secretary, Dr. J. D. Rolleston; Vice-Presidents, Sir D'Arcy Power, Dr. Tricot-Reyer, Dr. E. Jeanselme, Dr. E. Menetrier.

Obituary.—Colonel Harry Littlewood, late Professor of Surgery in the University of Leeds, died suddenly on December 19 at Aylsham, Norfolk. He retired at the age of 53 to his native county, Norfolk. He was a good surgeon and an able teacher, respected by all and beloved by those who knew him intimately.

Dr. George Henry Darwin died in Manchester at the age of 69 on December 6, after an illness of a few weeks. Dr. Darwin's reputation will rest mainly on the good service he rendered to ambulance work and training. He was better versed probably in railway ambulance work than any man in the country and lectured in all parts of the country on this subject. During the war he served as medical officer to one of the branches of the Second Western General Hospital in Manchester.

2. Recurrent Renal Calculi. J. Dellinger Barney.
3. Experiences with the Use of Radium. George C. Wilkins.
4. The Practice of Medicine in Massachusetts. A Discussion of the Law Governing the Registration of Physicians. Benjamin Loring Young.

2. Recurrent Renal Calculi.—J. Dellinger Barney presents an analysis of 139 cases of kidney stone occurring in the genitourinary department of the Massachusetts General Hospital, of which 108 were men and only thirty-one women. Only eleven of these patients were past fifty years of age. One might almost say that renal stones were uncommon during childhood and old age. With present day diagnostic methods there should be little or no reason for operating on the appendix or some other organ when a renal stone is the real offender. Renal stone may be most insidious, and may acquire enormous size with practically no symptoms at all. In only 43 per cent. of the writer's cases was there any tenderness in or in the region of the stone-bearing kidney at the time of examination. Pus was the most frequent element in the urinary sediment, being found alone fifty-nine times and combined with blood forty-one times. More important is the fact that in twenty-six cases blood alone was found in the sediment, while in 8.6 per cent. of the cases the urine was persistently negative. This substantiates the observations of Cabot and Braasch. A positive *x*-ray was recorded in 125 cases, but it must be remembered that the roentgenogram will fail to show stones in from 6 to 11 per cent. of cases. In the examination of the *x*-ray film one must remember that superimposed stones may and frequently do give but one shadow, so that on this evidence alone no one can be sure of the exact number of stones present. While cystoscopy and catheterization of the ureter alone may be of little diagnostic value in renal calculus, at the same time it is a procedure which is essential in most instances. Expert interpretation of the *x*-ray plate is essential, for there are many shadows which resemble urinary calculi to the inexperienced eye, whereas the practiced observer will at once pronounce them to be phleboliths, calcified mesenteric glands, calcified costal cartilages or extraneous fecal material. Cystoscopy, with gentle manipulation, often brings about conditions favorable to the passage of calculi. The mortality in this series of cases was 3.5 per cent. It is doubtless true that conditions that produce stone are still active after operation, but it is also true that the operator did not remove all stones in a large num-

ber of cases. Of twenty cases in which an *x*-ray was taken during convalescence, nine, or 45 per cent., showed stones still remaining in the kidney. It is of vital importance that an *x*-ray be taken during convalescence, for one taken six months after operation cannot distinguish between a "left over" and a recurrence. It is also important that an *x*-ray be taken as close as possible to the time of operation, preferably the same day, the reason being that a stone may travel back and forth between the renal pelvis and the lower end of the ureter without producing symptoms. The old-fashioned method of needling a kidney, especially at the suspected location of the stone, is often helpful. In spite of the high percentage of recurrence the patient should not be encouraged to carry about with him a stone which is surely but insidiously doing damage to the kidney. In most instances a pyelotomy will suffice to remove the stone, and there is small risk attending this procedure. Even though nephrectomy is deemed necessary, the mortality is not terrifying, nor should the chance of secondary hemorrhage act as a deterrent.

1. The Relation of Medical Education to Medical Progress.—Henry S. Pritchett. (See MEDICAL RECORD, Vol. 3, No. 23, p. 1003.)

2. The Recognition of Impaired Renal Function.—George Morris Piersol discusses those tests of renal efficiency which in his personal experience have proved to be of practical value and which may be readily employed in private practice and in the ordinarily well equipped hospital. One of the most useful tests of renal function is a study of the variations in the volume of urine and the specific gravity. In general the importance of this test is not appreciated. It is advisable to conduct these observations on an ambulant patient who is following a usual routine and taking an accustomed diet. Fixation of the specific gravity at too high or too low a level is strongly suggestive of impaired renal function and calls for further investigation. In patients who are on their accustomed diet, valuable data in reference to the suitability of their dietary can be obtained from the Mosenthal two hour test for urinary concentrations and volume, if the sodium chloride and nitrogen excretion is estimated. The estimation of the urinary nitrogen alone does not furnish information in regard to nitrogen retention; this can only be ascertained by estimating the blood uric acid, urea and creatinine. It seems established that the phthalein test is of little value in the early diagnosis of nephritis. In the acute forms of nephritis it is of doubtful significance both diagnostically and prognostically. The chief value of the test is found in the chronic nephritides. In these renal conditions, provided edema is not marked, it is of definite prognostic import and it also furnishes a valuable guide as to the effects of treatment. Provided extraneous causes of chloride retention are eliminated, we have in delayed or defective salt elimination a useful early index of renal impairment, more especially in the tubular varieties of nephritis. Since salt retention is found more especially in the tubular and parenchymatous types of nephritis, whereas delayed nitrogen excretion is more common in the glomerular forms of renal disease, these tests may be helpful or confirmatory in the diagnosis of the various types of renal disease. The earliest evidence of renal inefficiency, as shown by an increase in the nonprotein nitrogen elements of the blood, is an increased concentration of blood uric acid. The most generally valuable clinical and diagnostic measure of kidney function is the retention of blood urea nitrogen, and the functional test of gravest prognostic import is an accumulation of creatinine in the blood. Of less general application is the determination of the chlorides in the blood. In certain types of renal disease, more especially those associated with water retention and edema, the estimation of blood chlorides furnishes a valuable functional test. The chlorides are best estimated by the method of McLean and Van Slyke. The above mentioned tests by no means include all the functional tests advocated, but those that have been omitted have been discarded either because they have not been tested out sufficiently to demonstrate their value or because they have already proved too inaccurate or cumbersome for routine clinical use.

4. Early Diagnosis of Brain Tumor Before Eye Symptoms Occur. Differentiation from Encephalitis and from Hysteria and Emotivity.—Tom A. Williams points out that a hysteriform syndrome is a common initial manifestation of the presence of a new growth in the brain. The difficulty of the diagnosis is further complicated by the error perpetuated in textbooks that the alterations of the visual fields in these cases are stigmata of hysteria. Nowadays it is known that inversion of color fields or restriction of the form fields are indicative of physical damage and are not characteristic of hysterical patients who are properly examined. Another complication making the diagnosis difficult is arterial hypertension, for the signs found may then be attributed to arteriosclerotic lesions. It must be remembered, however, that hypertension may be secondary to disturbances of the vasomotor center. In both pellagra and encephalitis the focal signs associated with brain tumor may be conspicuous. In that case they may be difficult to distinguish, unless the patient is seen during the acute stage or a good history is obtained. However, it is unusual to find as intense impairment of function as would be caused by a neoplasm, nor would the signs be widespread unless there were also the classical symptoms of headache, vomiting and papilledema, along with modification of the visual field. If the clinical picture is not distinctive to an experienced neurologist, the progress of the case will enable a diagnosis to be made before the tumor is too large to intervene surgically. Hysteria should never be diagnosed by exclusion, but only after the discovery of the suggestion which has determined the hysterical behavior.

8. Enteroantigens in the Treatment of Noncontagious Chronic Disease.—B. Sherwood Dunn, believing that the origin of the chronic diseases of noncontagious character is found in the intestine, caused by albuminoids or microbic products obtained in the intestine which find entrance into the blood current through the congested and at times inflamed mucous membrane, which, acting as antigens, determine an anaphylactic condition of the organism, he has treated these diseases by the injection or ingestion of microbes taken from the intestinal flora. The mixture is composed of all varieties of microbes found in the intestinal contents. The quantity of microbes injected or ingested is governed by weight: one 1 1000 to 1/200 milligrams of microbes for the injection and one to five-tenths milligrams for ingestion. In all, some 352 cases have been treated, comprising dyspepsias, constipation, enteritis (mucomembranous), chronic appendicitis, sigmoiditis, urticaria, asthma, emphysema, rheumatism, dysmenorrhea, leucorrhea, mild chronic albuminuria, neurasthenia, melancholia, insomnia, migraines, tuberculosis of the skin, mucous membranes, testicle, kidney, glands and a few cases of the lungs. The most important conclusion drawn from these cases is that the enteroantigens produce a curative action without any noticeable harmful reaction. Enteroantigens possess an incontestable superiority over antigens of peptones, milk and serums employed in similar cases. From the theoretical standpoint Dunn suggests that the curative action of these enteroantigens is not specific, but is antianaphylactic; the action is not exercised directly upon the lesions, but

through the medium of the central nervous system and more particularly through the bulb, causing a stimulating action or correction of the functions of the glands. Of all known antigens the anteroantigens exercise the greatest elective action upon the central nervous system.

12. The Tuberculin Treatment of Tuberculosis by the Nasal Insufflation Method.—J. P. Israel has used the insufflation method, using powdered B. E. tuberculin and carrying out as nearly as possible the method of Paget (MEDICAL REROD, vol. lxcv, p. 148, January 25, 1919). This method of treatment consists in insufflating one ten thousandth mg. tablet of tuberculin B. E. every other day, until six doses have been given, providing the patient does not show any marked reaction. The dose is then increased to one six thousandth mg., given every other day, until six doses have been administered. This method of administering tuberculin has great advantages over other methods and can easily be used by any physician. In most cases uniform results are produced. The period of treatment should extend over six to eight weeks at least. This, in the writer's opinion, is the method par excellence for the treatment of ocular tuberculosis.

1. Faulty Food in Relation to Gastrointestinal Disorder.—Robert McCarrison produces evidence to show that much of the gastrointestinal disorder of civilized people at the present day is due to faulty food. He compared the incidence of such disorder among civilized communities and its comparative absence among certain races living under more natural conditions, and contrasts in general terms the food habits of the former with those of the latter. For some years he has been engaged in a study of the effects of deficient and ill-balanced food on the various organs and tissues of the body, as observable in animals fed on such foods under experimental conditions. The foods used were those deficient in all three classes of vitamines, in suitable protein, in fats, and excessively rich in starch; foods deficient in vitamines B and C and excessively rich in starch and fats; foods deficient in vitamines A and B, but well balanced in other respects. The data afforded by specimens from the gastrointestinal tract of pigeons, guinea pigs and monkeys permits certain broad conclusions, namely: (1) The health of the gastrointestinal tract is dependent on an adequate provision of vitamines. The absence of growth vitamines is capable of producing pathological changes in the tract which frequently assume the clinical form of colitis. Deficiency of vitamine C is especially concerned in the production of congestive and hemorrhagic lesions in the tract, and evidence of these may be found in animals which have not exhibited during life any of the clinical manifestations of scurvy in noteworthy degree. (2) The disorder of the gastrointestinal tract, consequent on vitamine deficiency, is enhanced when the food is ill balanced. (3) The pathological processes resulting in this situation from deficient and ill-balanced foods are congestive, necrotic and inflammatory changes in the mucous membrane; degenerative changes in the neuromuscular mechanism of the tract; degenerative changes in the secretory elements of the tract; toxic absorption from the diseased bowel; impairment of the protective resources of the gastrointestinal mucosa against infecting agents. The use of faulty foods in human beings has a direct relation to such disorders as infantile diarrhea, jail dysentery and asylum dysentery, dyspepsia and gastric dilatation, gastric and duodenal ulcer, intussusception, colitis and failure of colonic function. No inconsiderable proportion of modern populations are existing on food supplies more or less deficient and ill balanced.

5. Transfusion Reactions and Citration with the Needle.—Frank W. Hartman holds that nonhemolytic transfusion reactions are largely due to incipient coagulative changes in the transfused lood. These changes are probably caused by injury to the platelets with the formation of thromboplastin and thrombin. To prevent injury to the platelets contact with foreign substances should be avoided as far as possible, and aeration and loss of body heat should be avoided. The anticoagulant should be added as the blood leaves the vein of the donor. The writer has devised a compact and easily manipulated apparatus which citrates the blood within the needle. By the employment of this apparatus he has reduced the number and severity of reactions 50 per cent.

6. The Present-Day Sources of Common Salt in Relation to Health, and Especially to Iodine Scarcity and Goiter.—Emery R. Hayhurst calls attention to the fact that authorities are agreed that goiter is infrequent in both animals and man along the sea. The sea is the great storehouse of iodine, where it completes a cycle from inorganic compounds to organic life and return. The great solubility of iodine accounts for its almost complete absence from the land surface and, perhaps, for some of the peculiarities noticed in regard to the incidence of goiter. While iodine may occur in natural deposits along with chlorine, usually in the form of the sodium salt, it is never obtained from such sources commercially. Common salt for dietary purposes should include not only sodium chloride, but also sodium iodide, and undoubtedly many of its other original concomitants. If it is not obtained from sea water, it should be handled commercially in a manner to retain these constituents.

9. Abdominal Migraine.—William A. Brams states that abdominal migraine occurs chiefly in those who suffer from typical head migraine or when there is a history of this disease in the family. The disease manifests itself by periodic attacks of epigastralgia with nausea and vomiting, and occasionally with diarrhea. Physical examination reveals no definite signs of any kind. The patient is free from all symptoms during the intervals between attacks. The attacks last a few days and begin and end rather abruptly. The disease is refractive to all treatment, but is favorably influenced by antimigraine therapy. In view of the frequent presence of disturbances in the female pelvis it is suggested that a course of ovarian extract be tried in these cases in addition to the regular arsenic and antimigraine measures.

10. Spontaneous Labor in a Case of Decentralized Uterus.—Dan Collier Elkin reports a case of cervical Pott's disease, with an almost complete transverse lesion of the seventh cervical segment, in which pregnancy went to full term, when normal and almost painless labor occurred. Attention is called to the fact that cases of this kind serve to place the uterus among the autonomic organs of the body and indicate that the initial stimulus to labor originates by some other mechanism than cerebral control.

11. The Cure of Infantile Rickets by Sunlight, Accompanied by an Increase in the Inorganic Phosphate in the Blood.—Alfred F. Hess and Margaret B. Gutman submit evidence which shows that sunlight not only brings about a clinical cure of the characteristic lesions of rickets, but also brings about an increase in the inorganic phosphate of the blood similar to that noted when the cure is accomplished by means of the specific cod liver oil. This observation is of interest both as additional testimony of the curative value of sunlight in this disorder, and as evidence that the curative process occasioned by these divergent therapeutic agents will prob-

ably be found to be fundamentally the same. These results furnish a chemical basis for the use of heliotherapy in rickets. Furthermore, they furnish the first definite evidence of metabolic change in the animal body brought about by the solar rays.

11. A Fatal Case of Delayed Neosalvarsan Poisoning. D. R. C. Shepherd.

1. The Origin of the Anginal Syndrome.—Charlton Briscoe, in following up some of his work having to do with the mechanism of lung expansion and the action of the accessory muscles concerned in respiration, has come upon facts which seem to bear a definite relation to the origin of the anginal syndrome. Briefly, these facts are as follows: Overfatigued muscles give rise to referred pain in distant areas. The upper respiratory mechanism is excessively active under the same conditions in which attacks of angina pectoris occur, and stress of this nature affords a better explanation for nocturnal attacks than does cardiac strain. The respiratory muscles of this region, when hypersensitive, are the last structures in the segment to lose local tenderness and the faculty of producing referred pains by pressure. When these muscles are hypersensitive and subjected to pressure the areas to which pain is referred correspond to those similarly affected in angina pectoris, and are frequently recognized. The author has demonstrated a phenomenon which offers an explanation for the warning and sequence of pain in angina pectoris. This is dependent upon irritation of one of the expiratory muscles involved, and results in marked thoracic elevation. Treatment by alleviating the stress of these muscles has frequently—not always—been effective in relieving the pain *without* other treatment. Two attacks of angina pectoris have been observed as the result of irritation of the respiratory muscles. The phenomena generally which accompany an attack of angina pectoris can equally well be explained on a respiratory hypothesis as on one of vascular origin. It is of further significance that the age incidence of angina pectoris corresponds with that of ossification of the ribs and cartilages—a source of increased difficulty in respiration.

4. Alimentary Infections in Chronic Arthritis.—N. Mutch presents the results of observations made on 200 cases, half of which were hospital patients and the other half private patients. Gout, venereal or tuberculous disease of the joints, and all cases of nonarthritis were excluded, but otherwise no selection was exercised. He finds that the condition of the alimentary tract dominates the outlook in rheumatoid and osteoarthritis. The general scheme employed in the treatment of the present series of cases was as follows: The entire alimentary tract was surveyed carefully in each case and an estimate formed of the relative degrees of septic absorption occurring at the various levels. The more accessible areas of infection in the jaws, throat and intestines were treated surgically, and all the disorders of the digestive tract which had encouraged the development of chronic infection were dealt with. Autogenous vaccines proved of great value when used to supplement these measures. They were prepared from infective bacteria of all the principal zones of sepsis. Streptococci obtained from different foci in the same patient usually vary in their cultural characteristics, and each strain was included in the vaccine. Chronic infection frequently damages the thyroid gland. In the present series minor forms of subthyroidism were very common, while well defined myxedema or goiters of considerable size were seen in 14 per cent. of the cases. There is an intimate association between immunity reactions and the functions of the thyroid gland. The dry extract of the thyroid was given in all such cases with great benefit to the joints. In the present series of cases, which have been followed for varying periods up to nine years, 89 per cent. show very marked improvement or complete arrest. If it had been possible to exclude those cases in which circumstances such as age, temperament, and position in life prevented the full use of radical methods the results would have been still more encouraging.

5. The Problem of Chronic Suppuration of the Middle Ear, with Special Reference to Ionization.—Arthur G. Wells asserts that while ionization has been established as one of the most valuable and satisfactory means known for the treatment of chronic suppuration of the middle ear, the method has at present definite limitations. The indications for ionization in this disease, as observed in personal experience of some hundreds of cases, permits the following group to be described as unsuitable: (a) Cases which present large granulations and polypi in the tympanum; (b) cases where there is any disease of bone either of tympanum or mastoid; (c) cases where the antrum is diseased; (d) cases where there is disease of the Eustachian tube; (e) cases with any nasopharyngeal condition favoring reinfection of the ear; (f) cases where perforation in the membrane is so small that fluid cannot pass satisfactorily from the meatus into the tympanum. The cases suitable for ionization are those in which the ionizing fluid can reach the whole area of suppuration. The results of ionization in chronic suppuration of the middle ear in this series show a cure in about 60 per cent. of the cases. In some cases one ionization is sufficient; in others two and even three ionizations are needed. Besides being a valuable method of treatment, ionization is also in many cases an important aid in diagnosis. It frequently happens that in examining an ear, a little pus can be aspirated from the antrum or aditus; it is hard to say definitely whether the antrum is too far diseased to hope for a cure by ionization, and whether the proper treatment should not be a mastoid operation. Ionization frequently clears up this point; failure to effect a cure or any improvement justifies the assumption that disease of the antrum is sufficiently far advanced to call for mastoid operation. Ionization is also valuable as a part of the after treatment.

1. Respiratory Phenomenon in Nervous Disease.—J. Purves Stewart discusses respiratory symptoms in cerebral lesions, due to concussion, hemorrhage, thrombosis, or embolism; those due to cerebral meningitis, cerebral abscesses or intracranial tumors, and those due to bulbar lesions, spinal cord lesions, peripheral nerve lesions, and muscular affections. When respiratory affections are due to these causes they are mainly paralytic. The spasmodic respiratory affections may be due to disease either of the vegetative or the cerebrospinal nervous system. With regard to the vegetative nervous system, the most important spasmodic affection is asthma, whose phenomena of labored breathing consist essentially in spasm of the nonstriped bronchial muscles, enervated by the dorsal motor nucleus of the vagus. Coughing, yawning, sneezing, and hiccough are all of them reflex phenomena which may be induced in healthy individuals by appropriate stimuli. Of these hiccough calls for special mention. It is a spasmodic myoclonic contraction of the diaphragm, occurring so suddenly that the glottis is suddenly closed by suction, producing the characteristic inspiratory noise. Hiccough is sometimes

excited by transient gastric or other abdominal irritation; it may be due to disease of the peritoneum in the region of the diaphragm (the phrenic nerve being sensory as well as motor in function). Other cases of hiccough are due to central disease of the respiratory centers in the medulla; thus it may be produced by the toxin of epidemic encephalitis. Hiccough of this kind may continue for days at a time, at the rate of twelve to fifteen hiccoughs per minute. Hiccough may also occur as a terminal symptom in tumor of the posterior fossa of the skull. One may also meet with cases of hysterical hiccough, which are recognized by their history and concomitant phenomena, and the symptom promptly subsides under appropriate suggestive treatment. Other spasmodic affections in which the respiratory mechanism is upset are whooping cough, laryngismus, tetanus, rabies, major epilepsy, athetosis, chorea, and exophthalmic goiter. Various respiratory phenomena may be met with in hysteria. Of these hysterical cough is the commonest, but rapidity of respiration, hysterical sobbing, and all sorts of curious laryngeal noises may be met with in different cases, but whatever their variety they cease during sleep. Hysterical cough is unaccompanied by true dyspnea, while abnormal physical signs in the respiratory organs are conspicuous by their absence. Hysterical rapidity of breathing is without cyanosis or other respiratory distress, and the pulse remains quiet and steady. Respiratory tic or habit-spasms are frequently noted in highly strung, often highly intelligent, individuals of psychasthenic nervous constitution. Such persons are not necessarily mentally subnormal; on the contrary, some of them are far above the average of intelligence. These respiratory tics are psychomotor affairs of cortical origin, and never interfere with voluntary movements.

3. The Bacterial Action of Gastric Juice on B. Tuberculosis.—John Inkster and S. Roodhouse Gloyne describe experiments carried out with gastric juice removed from the stomachs of persons free from gastrointestinal disease, at various intervals of time after an oatmeal test meal. They find that such gastric juice shows very little power of destroying tubercle bacilli in sputum which has been exposed to it for ninety minutes, and tubercle bacilli in mouth washes which had been exposed to it for ninety and 180 minutes respectively. In one case a total acidity of 62, in another 54.1, and in a third of 24 failed to destroy the bacillus. It would seem that the protection against the tubercle bacillus afforded by the gastric secretion is apparently by no means perfect. But it must be remembered that the dilution of contents and the motor activity of the stomach probably play a large part in this mechanism of protection, and these latter factors cannot be properly experimented upon *in vitro*. The results in these experiments are in general agreement with the conclusions arrived at by Allan Macfadyen under different conditions and with bacteria other than *B. Tuberculosis* as long ago as 1887. The writers know of no records which show whether or no tubercle bacilli have been found in gastric juice in persons not suffering from clinical tuberculosis. None were found in these individuals. It would be interesting to have this point cleared up, as it may have an important bearing on the portals of entry of the bacillus.

4. An Operation for Inguinal Hernia.—G. Lenthal Cheatle claims that by this method one is enabled to deal with certain difficulties that are sometimes met with in the excision of the sac. He makes a transverse skin incision four or five inches long and one and one-half inches above the symphysis pubis. A transverse incision is then made in the aponeurosis of the rectus abdominis of both sides, care being taken not to injure either linea semilunaris. The linea alba is undercut upward and downward, to within one or two inches of the umbilicus and pubis respectively; in doing so the sheath of each pyramidalis muscle will be opened. The opening thus made is retracted upward and downward and the subperitoneal tissue exposed by separating the abdominal muscles in the midline. The peritoneum and its contents are pushed up on each side and if necessary kept up by packing. A lower retractor pulls the abdominal wall downward, outward, and forward. Its prongs should reach the deep epigastric artery and vein. The upper retractor pulls the structures outward. This exposes the iliac fascia and the neck of the sac. The sac is then cleared and pulled out of the canal. If there are no indications of the possibility of its easy extraction, the sac is cut and the canal portion replaced. The remains of the sac in the peritoneal space are then radically excised. The neck of the sac, including part of the parietal peritoneum, is then transfixed and removed. Finally the inguinal canal of the opposite side is examined. Hernia which should not be selected for this operation are direct hernia, irreducible enteroceles, hernia in male children under seven or eight years of age, and old hernia in which the internal opening has been dragged down opposite the external. The procedure is suitable for hernia in females of any age, and all uncomplicated inguinal hernia in males over seven or eight years of age.

Le Bulletin Médical.

December 3, 1921, xxxv, 49.

Monilia Pneumonia.—Assimis announces the existence of a type of chronic pneumonia due to conidia—a conidiosis. The organisms in question are visualized as perfect fungi which through ascoform reproduction have become degraded. They can be cultivated especially on Sabaraud's medium and are pathogenic to man, causing lesions of the skin and mucosae. As a specific cause of bronchitis they have been known since 1905, although the *Monilia* bronchitis is but one of a family of bronchial mycoses. The family in question is usually regarded as of tropical incidence, but the *Monilia* form at least has been seen as far north as Great Britain. The author, who is familiar with the bronchitis of this origin, announces that the same fungus can cause chronic pneumonia and relates a case seen by him in Athens, which ended fatally. The victim was a man of 58, whose family were down with influenza. For several years he had coughed, but ascribed this to tobacco. While caring for his family his cough became worse, and he began to spit blood. The diagnosis was pleurisy, and patient was sent to the hospital for incision. Several punctures were negative. At this juncture the author took charge of the patient. The dullness certainly suggested a pleuritic effusion or a tumor—nothing else could have caused such absolute dullness on percussion. The *x*-ray, sputum examination and puncture threw no light on the diagnosis. The accompanying fever fell under quinine, the man being an old paludic. Persistent sputum examination finally brought to light the Monilia. The patient eventually became adynamic, and vomitinfi and diarrhea set in, frequent and profuse, until the subject died of exhaustion. An autopsy was not permitted. The patient lived over nine months after the first appearance of fever, so that clinically the case bore no resemblance to pneumonia, ranking rather in this respect with the chronic affections such as tuberculosis, syphilis, actinomycosis, and cancer.

Wiener klinische Wochenschrift.

November 17, 1921, xxxiv, 46.

The Shiga Bacteriophages.—Bail refers to the filtrable organism which is able to exert a purely specific lytic action on the Shiga bacillus. This as yet invisible organism was first discovered by d'Herelles of the Pasteur Institute, Paris. Before this Salambeni had shown that certain myxomycetes could exert a similar action on bacteria. One strain of stool filtrate can act on the Shiga in incredible dilution. Aside from this, however, quantitative relations can be determined between the lytic solution and the bacteria dissolved. As is known the bacteriophages can proliferate in suitable media, and it is because of this ability to multiply that the invisible virus is known to be living. That different varieties or strains of bacteriophages occur may be shown in various ways, chiefly by the different ways in which smears of Shiga bacilli are attached. In animal experiment the injection of bacilli cultures (Shiga) into the peritoneal cavity produces an antisubstance which is bacteriophagic. Under these conditions the formation of bacteriophages is a defense reaction, but bears no relationship whatever to leucocytosis. The fact of its restriction to this particular bacillus robs the discovery of any practical interest. From another angle the pure cultivation of normal Shiga bacteria in certain media has led to the formation of the bacteriophages.

Book Reviews.

THE GLANDS REGULATING PERSONALITY, A Study of the Glands of Internal Secretion in Relation to the Types of Human Nature. By LOUIS BERMAN, M.D., Associate in Biological Chemistry, Columbia University; Physician to the Special Health Clinic, Lenox Hill Hospital. New York: The Macmillan Company, 1921.

THIS is the most interesting and enlightening book on endocrinology that the reviewer has ever read. It reads like a novel, and holds the attention from start to finish. The author presents not only his first-hand knowledge of the subject, but also his conclusions from a complete and discriminating study of the vast literature.

Most practitioners are too busy to study clinical endocrinology, and many physiologists, who can determine only the evident demonstrable effects of *total* extirpation of glands, *i.e. operated* animals, will not accept the clinical facts that there are all grades of over- and under-secretion of these glands, which not only cause symptoms but, as the author so well describes, modify character and cause all kinds of normal and abnormal impulses.

One need not accept every conclusion at which the author arrives, but this book represents a basic platform of generally accepted facts, of partially accepted probabilities, and of unproved possibilities from which can be built up by laboratorial, pathological, and clinical investigations one of the most important biological and chemical sciences of the age.

Life seems to be made up of chemical and electrical reactions. The vitamines are probably necessary for the activation or for the chemical composition of the hormones manufactured by the endocrine glands, hence their vital importance. Doubtless the character of the food, the climate, the environment, the infections suffered, and the type of glands inherited all, as the author urges, modify and determine the amount and efficiency of the hormones produced by the endocrine glands.

Every practising physician should, unprejudiced, study all that is known of the endocrine glands, and of the effects of chronic, as well as acute, focal infection (as chronic focal infection always injures one or more glands by toxins), and then use the knowledge thus acquired in the treatment and management of his patients.

It is not necessary to discuss the book in detail. It is sufficient to recommend that this book be carefully read, and the reader will then be the better equipped to understand and treat his patients.

RADIANT ENERGY AND THE OPHTHALMIC LENS. By FREDERICK BOOTH. Introduction by WHITEFIELD BOWERS, A.B., M.D. Price $2.25. Philadelphia: P. Blakiston's Son & Co., 1921.

THIS volume claims to be no more than a clear and complete treatise on refraction. The number of text pages is 226 and of illustrations 230. The thirteen chapters are devoted in the following order to Anatomy, Physics of Light, etc., Radiant Energy, Vision, Refraction, Accommodation, Convergence, Cycloplegics, Visual Acuity, Retinoscopy, Ophthalmoscopy, Transposition, Fitting and Prescribing and Mathematics. A survey of the book appears to bear out the claim of Dr. Bowers that the assemblage of facts and arrangement of the material leave nothing to be desired in a work of this scope. Owing to the large number of text figures and the large print the actual number of words in the book is relatively small, but the subject matter is compressed to the utmost. Thus the chapter on Vision occupies but a little over two pages, while Einstein's gravitational theory of Light is summed up in a little over a page.

MODERN ITALIAN SURGERY AND OLD UNIVERSITIES OF ITALY. By PAOLO DE VECCHI, M.D., Corresponding Member of the Royal Academy of Medicine, Turin; Fellow American College of Surgeons. Foreword by GEORGE D. STEWART, M.D., President New York Academy of Medicine. With fifteen full-page illustrations. Price $5.00. New York: Paul B. Hoeber, 1921.

THIS is a very delightful as well as vitally instructive work, which really is a product of the war. It tells of the great advance medicine and surgery have made in Italy since the war; of the part Italy took medically during the war, and the results now for Italy since her enormous medical stride. Dr. Stewart, in his foreword says: "The achievements of Italy in Medicine and Surgery during the last war, however, have been so great that the world can no longer fail to notice them. . . . It is with the hope of promoting and fostering such an understanding that Dr. Paolo De Vecchi, an eminent and learned Italian, who studied at the University of Turin, and has spent his entire professional life in America, has written this volume." It is a book to be recommended for its presentation of such unusual data and for the excellence of its production, which in this age of hurry and lack of attention to details, is indeed a fact to be noted, not ignored.

CLINICAL LECTURES ON ENLARGEMENT OF THE PROSTATE, With a Description of the Author's Operation of the Total Enucleation of the Organ. By SIR PETER J. FREYER, K.C.B., M.D., M.Ch., M.A., LL.D., etc., etc. Surgeon to St. Peter's Hospital, London, etc., etc. Fifth edition. Price $3.25. New York: Wm. Wood & Co., 1921.

THE fourth edition of this well-known work has been for some months out of print, the appearance of the fifth having naturally been delayed through the interruption of the war. The lectures which comprise the monograph have in the meantime been amplified and brought up to date. Many new case histories have been added without eliminating any of the original ones. A special new lecture is devoted to cancer of the prostate. The total material of complete enucleations now stands at 1625 cases and of this number 221 were malignant and all but four of these cancerous. These prostates were diagnosticated as cancer and according to calculations of certain pathologists at least an equal number must have been masked as benign growths. A classic work like this should be in the library of every practitioner.

HANDBOOK OF SKIN DISEASES By FREDERICK GARDINER, M.D., B.Sc. (Public Health), F.R.C.S.E. Lecturer on Skin Diseases, University of Edinburgh; Physician for Diseases of the Skin, Royal Infirmary, Edinburgh. E. & S. Livingstone, Price $2.00. New York: William Wood & Co., 1920.

THIS little work of 160 pages embodies the author's experience as a lecturer, whence the absence of a rigorous classification. The common dermatoses are first considered, for the student will for the most part enter into general practice and should learn something of the more prevalent diseases. Only essentials can be discussed in so small a volume, hence the aim is terse description supported by forty-six illustrations. While following the Edinburgh school of dermatology as exemplified by Jamieson and Norman Walker, the author has drawn on English, American, and Viennese authority and has given his own personal views when it seemed desirable. In more detail, the book comprises fifteen lectures by the author on the following subjects: streptococcic and staphylococcic dermatoses; diseases due to animal parasites; seborrhea and congeners; psoriasis; infections of the hairy scalp; urticuria and erythema; bullous eruptions; prurigo and lichen; pityriasis; tuberculosis and tuberculides; pigment anomalies; neoplasms and syphilides.

ÉTUDES D'HYDROLOGIE CLINIQUE. Edited by ROGER GLÉNARD. Paris: L'Expansion Scientifique Française, 1921.

THE responsible editor for this serial volume is Dr. Roger Glénard of Vichy, who is, we believe, the son and successor of Glénard of enteroptosis fame, deceased not long ago. In the first number (April, 1921), in addition to articles by the editor, there are six others by other collaborators, Labbé, Flurin, Heitz, Joly, Palliard and Verdaile, each dealing with some aspect of diabetes, comprising the treatment of that disease at the hydromineral stations at Bourboule, Vittel and Royat, the venous circulation of the diabetic, and rhinopharyngitis and bronchitis in the same class of patients.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held November 22, 1921.

DR. HAROLD BAILEY IN THE CHAIR.

Hydatidiform Mole.—Dr. MILTON A. SHLENKER reported this case. He said that this condition was supposed to occur only once in 2,400 cases. He had had occasion to present two other specimens before the section within the year. He presented this case before the section because of its typical symptomatology and the great difficulty they had in coming to a conclusion. The patient, a woman thirty-five years of age, came under observation on July 18, 1921. She had been married fourteen years, had four children, and no miscarriages. Her husband was well. Her father died of carcinoma of the stomach at the age of forty-five years. Her appetite was poor, she was habitually constipated, and had had stomach trouble for the past ten years. She stated that a doctor had told here that she had gallstone attacks. She began to bleed on June 1. She continued to bleed and passed clots, though she did not experience abdominal pain until she was admitted to Gouverneur Hospital on July 18. Abdominal examination at this time revealed no tenderness or tumor. Vaginal examination revealed a lacerated perineum, rectocele and cystocele, and bilateral laceration of the cervix. The uterus corresponded to a three months' pregnancy and was in the normal position. Palpation of the adnexa showed a round hard mass the size of a hickory nut on the left side, which was very tender on palpation. The patient's teeth were in bad condition, and on July 21 she complained of an abscessed tooth, which was removed. On the following day she seemed much better. The bleeding had stopped. The uterus was still enlarged and the cervix firmly closed. The diagnosis was threatened abortion. The patient insisted upon leaving the hospital against advice. On August 29 she was readmitted. She stated that bleeding had recurred and had been more or less continuous. About three weeks before she noticed that she began to sweat, and complained of backache, headache and difficult vision. She passed dark urine freely and had a bad taste in her mouth. The uterus was large, globular, and extended a little above the umbilicus. No fetal heart sounds were heard, nor was ballottement present. There was also marked edema of the vulva and lower extremities. The blood pressure was 170 systolic, 90 diastolic. The specific gravity of the urine was 1,034; albumin 4 plus, and many leucocytes, granular casts and red blood cells were present. The temperature was normal. On September 2 interruption of pregnancy was decided upon for a supposed toxemia. The cervix was packed with iodoform gauze. Three days later the patient was bleeding profusely. She was removed to the operating room and the cervix dilated. On palpation of the cervical canal grape-like bodies could be felt, but no evidence of a fetus. With the use of a sponge forceps large quantities of this material was removed from the uterus. After operation the uterus contracted to about one-fourth its previous size. The pathological report stated that fragments of cyst wall and chorionic villi were found. The diagnosis was hydatidiform mole. The patient made an uneventful recovery, and was discharged on September 18, apparently well. On October 25 she was readmitted to the surgical division of the hospital with a history of more or less continuous bleeding. On October 25 she was operated on by Dr. Ladin and a large amount of tissue resembling placenta was removed. There was no evidence of products of conception. A laparotomy was performed and both ovaries found to be cystic, the right being the size of an orange, while the left was much smaller. A bilateral sapingo-oophorectomy was performed. The pathologist reported that the scrapings were simply hypertrophied endometrium and that the ovaries had undergone a cystic degeneration.

Death of Fetus in Twin Pregnancy Due to Twists in the Cord.—Dr. MILTON A. SHLENKER reported this case and presented the specimen to show a comparatively rare condition as a causation of the death of the fetus. The etiology of the condition was unknown, but it was supposed to be due to the movements of the fetus. Torsion or spiral winding of the cord was a normal condition, and was usually from left to right. It was said to begin about the third month of gestation. As a result of the atresia of the cord in this case there was complete absence of the jelly of Wharton. Death as a result of this condition was supposed to occur a few days prior to the delivery of the child. In this case the patient complained of excessive fetal movements about two weeks before her delivery, but had scarcely felt any life whatsoever after that period. The dead fetus was a male and decidedly more robust than the female child, which was delivered alive and in good condition. The first child to be delivered was the dead male. He presented a left occipitoanterior. The membranes were ruptured artificially, and much meconium was discharged in the amniotic fluid. On delivery the fetus did not breathe, nor was there any beating of the heart, and all efforts to establish respiration were without avail. The second child was delivered by a breech extraction and without difficulty. The specimen showed a single placenta with two cords, each coming from the opposite sides. Each child was contained in a separate amniotic sac. The placenta was elongated. The dead child was attached to the large half which, in the fresh state, was pale in color and tough to the feel, and there was more or less of a demarcation line from the other half of the placenta, which was apparently normal in consistence and otherwise.

Dr. H. C. WILLIAMSON said the toxic symptoms in the case of hydatidiform mole interested him. The patient had a low blood pressure and the urine showed albumin and casts, a kidney toxemia, which was cured when the hydatidiform mole was removed. This was an evidence that toxemia of pregnancy was due to syncytiotoxins.

Dr. WILLIAM P. HEALY said that Dr. Shlenker had had the very unusual experience of having had three cases of hydatidiform mole within one year. The symptoms were those of impending abortion. There was only one possibility of avoiding error, and that might have justified his making a diagnosis of hydatidiform mole when the patient first came under observation, and that was that the fundus was four inches above the symphysis pubis. That would indicate a uterus somewhat larger than it ought to be at that period. When the woman came under observation later, after having been home for a time, it was evident that she had a very large uterus, larger than it should be, and there were no fetal heart sounds. With these symptoms and the history of bleeding the diagnosis became an easier matter. The question that came up was whether when she was first seen she had the hydatid mole or whether it developed in an incomplete abortion. He did not see how that could be answered, but we knew that a careful examination of the secundines microscopically had shown a very high percentage of hydatid degeneration. It was more than possible that the patient might have incompletely aborted and later developed the hydatid mole.

Dr. BAILEY said that perhaps some of those present might remember that Dr. Vineberg reported before the New York Obstetrical Society a case of hydatidiform mole in which after leaving the hospital the patient had a frank hemorrhage. She was brought back and the uterus removed without further examination, and that uterus proved to have a chorioepithelioma growing in the fundus. The case brought up some discussion as to the advisability of going ahead and removing the uterus with only a history of bleeding following the removal of a hydatidiform mole. It might be recalled that some 13 per cent. of women having hydatidiform moles died in the first place, and 15 per cent. of the remainder developed chorioepithelioma. For this reason it was questionable whether the treatment should not be removal of the uterus. Dr. Bailey said he had always done as Dr. Shlenker did, that was dilate the cervix and attempt with the finger and sponge forceps to remove the hydatidiform mole. This woman should have had at the second operation a laparotomy and removal of the uterus. There were bilateral cysts of the ovaries which were simple cysts,

but nevertheless it would have been better for the women to have had the uterus removed, for it was probable that a chorioepithelioma was growing there. Dilatation of the cervix and removal of the mole by sponge forceps was the usual, but could not be considered as satisfactory treatment for this condition. As for the second case, it was exceedingly remarkable that that child should have grown to full size and did not die until a short time before birth.

Dr. SCHLENKER said the fetus was slightly macerated. From the history of the case it would seem that the fetus had been dead for two weeks.

Dr. BAILEY said it was still remarkable that the child should have grown all through the fetal period and obtained sufficient nourishment from that twisted cord.

Dr. SCHLENKER said Dr. Healy had inquired at what period of gestation this mole occurred. This might have been determined by a microscopical examination. After the third month of gestation the layers of Langham's and the syncytium became fused into a single layer. As to the removal of the hydatidiform mole, Dr. Schlenker said he would consider a panhysterectomy for this condition a rather radical procedure. It was his plan to carefully evacuate the uterine cavity, and thereafter to keep the patient under careful observation for quite a long period. Had the patient been returned to his service under the existing condition he would have performed a panhysterectomy, especially since this patient had bilateral cysts of her ovaries. It was now known that lutein cysts were an etiological consideration in chorioepithelioma. Dr. Schlenker said he was deeply interested in the case of twisted cord with death of the fetus because of its extreme rarity. He had been unable to find any great number of similar cases reported. He noted one reported case in which there were 348 twists in the cord. This fetus, while in fair state of preservation, showed some evidence of post mortem changes.

Notes on a Recent Visit to Austria.—Dr. I. C. RUBIN, in response to an invitation from the chairman, made this informal address. He stated that he had visited two places in a five and one-half weeks' visit abroad. One was Vienna, where he spent a longer time eight to twelve years ago, and where he was rather familiar with conditions as they existed before the war. The first impression upon one acquainted with Vienna prior to 1914, on arriving there now, was mingled sadness and depression. The people of Vienna formerly had the reputation of being a most genial, most welcoming, hospitable people, brilliant, easy-going, and cultured. In some respects the war has driven the whole people to the verge of despair, for there seemed to be "no bottom under their feet, no roof over their head." A great deal of movement was now noticeable—all in the mad struggle to get out of the mess they were in politically and the débacle financially. But it was a frantic motion on the part of the great multitude, with never a hope of rehabilitation. In spite of their culture and their wonderful esprit in letters and art but one thing was uppermost in their minds now, and that was the matter of "exchange." Some of the places of recreation were still there, but all was changed, the people were shabbily dressed, the charm and the ornament were gone. The "Ringstrasse" was now a shabby affair. During the first week Dr. Rubin said he tried to get into the spirit of the place and went to the Embryological Institute. There he found Professor Fischel in charge. It was remarkable to see the wonderful way in which he was carrying on his work. The atmosphere about his institute was that generally found in Vienna before the war. This man was moving his old institution into a new one, and was busy getting his new equipment. He said the government was allowing him 500,000 kronen, which was equivalent to about $2,500, to equip the new institution. Imagine equipping an institution like Roosevelt Hospital with $2,500! He said he hoped to get 250,000 kronen, when he would be in a fair way to complete the equipment. Nevertheless, in spite of all the drawbacks, remarkable scientific work was being done. After the first week, Dr. Rubin said he began to visit the old clinics. It was still vacation time, and although the men did not take long vacations it was a time when most of them were away. Professor Beham occupied the place formerly occupied by Schauta and Wertheim's place was occupied by Professor Kermanner, formerly Docent under Von Rosthorn, a man with whom Dr. Rubin had worked. Their facilities were absolutely short. The laboratory was not manned by the old chief; there used to be Professor Schottlaender at the head of the laboratory. He was a special gynecological pathologist who had been a gynecologist and a general pathologist, and finally devoted himself to gynecological pathology. Today a much younger man was there. The new chief had not yet gotten into the activities of the institution, but it was safe to predict a continuance of that essential scientific conduct of the work which characterized Von Rosthorn's and Wertheim's direction, for Professor Kermanner was a man of great scientific attainments and his personality would attract many students and workers. The *x*-ray department was continuing to do progressive work, and in operative work they were going ahead. They had developed a new operation for uterine prolapse, for example. Weibel of the Wertheim clinic had devised an operation for prolapse and Halban in the Wildener Hospital had also devised an operation for prolapse. Halban did not use the *x*-ray for carcinoma or myoma except in inoperable cases. He was a forward looking and thinking man, one of the most advanced men in gynecology abroad today, and his opinions were well worth considering. His surgical technique was so perfect that few could compete with him. His preference to use the operative procedures rather than the *x*-ray was perhaps explainable on the ground of his personal individual skill. His clinic was worth visiting, and his prolapse operation would probably gain many adherents. It consisted in separating the vesicovaginal fascia in the manner that Dr. Rawls did. He succeeded in getting the fascial plane in one or two minutes. He then separated the bladder and opened the peritoneum. He drew out the uterus and then pulled down the vesical peritoneum till it appeared tense. He thus got the peritoneum down to a point where the uterus would ordinarily be stitched in ventro fixation, between the symphysis and the umbilicus. Sutures were then taken through the peritoneum and the back of the fundus for fixation. Lower sutures were passed in such a manner as to obliterate the vesicovaginal pouch. He combined in one sitting vaginal plastic work with ventral fixation and claimed that with this method he had no recurrence of the prolapse. The operation was first described by him about two years ago. *X*-ray work in Vienna was pursued by two groups: those who used it intensively and it only, and of those there were few; and those who used it as an additional agency in gynecological procedures. In the Bettina Hospital, where Latzko did his work, they were doing extensive *x*-ray work. Where Wertheim was formerly chief there is also an *x*-ray department which was worth while mentioning. In the Kermanner clinic Von Graff preferred to use the *x*-ray for the relief of uterine bleeding in one form or another outside of carcinoma. He had devoted his studies particularly to bleeding at puberty. In this group of patients he seemed to be able to regulate the flow and establish normal menstruation. The matter of dosage had been so regulated that retention cyst follicles were destroyed and he left enough of the primary ovary and smaller follicles to carry on menstruation. If his work was substantiated his method would be of great help in the treatment of these cases. Most of the men in Vienna were excellent operators. That was why they still adhered to the surgical technique. In that respect we Americans, if one might be permitted to say so, felt the same way. It was just possible that the Germans were not as good technicians as the Vienna surgeons. However, he did not depreciate the surgery of the Germans Frankfort was the only town he visited in Germany, where he was anxious to see Seitz. Seitz and Wintz were responsible for the development of an apparatus which they had designed in cooperation with Dessauer, and they appeared to be men of great mechanical conception and skill. The thing Dr. Rubin was first struck with in Frankfort was the wonderful *x*-ray outfit which was shown to him. A striking difference was noticed between the ward patients in Vienna and those in Frankfort. In Vienna the ward patients were in a most deplorable condition; the bed sheets and supplies presented a condition of squalor not to be seen in the worst slums. It was amazing that good operative results

could be obtained in such surroundings. In Frankfort, on the other hand, in the wards the bed sheets were not such as were used before the war, they were not as spick and span but they were clean. The differences here, too, were due to the difference in money exchange. In Frankfort there was a university and the old hospital was under its auspices. Schmieden was head of the surgical clinic and Seitz was head of the gynecological department. At this hospital the inflammatory cases were not treated by operation but were treated conservatively. Laparotomy had been practically abandoned, though once in a while an exploratory laparotomy was done for carcinoma. The treatment for carcinoma and fibromyomata was with the *x*-rays and that left only a few plastic operations and ovarian tumors, and if the obstetrical surgeons did good work there were few plastic operations. So it would seem that we had better learn to use the *x*-ray. That was the most instructive thing he saw in Frankfort. Wards of patients with inflammatory disease were being treated conservatively; he did not see one of these patients operated upon.

Dr. Le Roy Broun asked how long the inflammatory cases were kept in the hospital.

Dr. Rubin replied that they remained from seven to twelve weeks. Myomata were not operated upon; that was in Frankfort. Nevertheless, it left the very suggestive impression with him that perhaps gynecology was leaning that way, though perhaps not to the extent it was carried there. Dr. Seitz treated all carcinomas with *x*-ray. They had no radium, though they had some mesothorium. There were cases in which they naturally used a combination of *x*-ray, mesothorium, and surgery. It was interesting to see what the Germans had done with two or three different procedures. With *x*-ray alone in carcinoma they succeeded in getting a permanent cure in all cases treated in about 24 per cent. With the operative treatment in Bumm's clinic they are getting cures in 30 per cent. of the cases. Bumm employed both surgery and *x*-ray and seemed to have cures in 60 to 70 per cent. of his cases. That was the position to take toward carcinoma. Where carcinoma was treated surgically, it was treated prophylactically with the *x*-ray afterward. Bumm operated almost 75 per cent. of the cases he got. It was pretty well known that they gave a very intensive treatment with the *x*-ray, and following the treatment the patients seemed to be in extreme shock. They were in pretty bad shape for ten days days or two weeks. They were temporarily in a worse condition than after the radical extensive operation for carcinoma. They looked as though they had been struck in the solar plexus by a terrific force. The cachexia was extreme. They were treated by transfusion and stimulation and they appeared to come around, but for the time being they made a very bad impression. The inflammatory cases appeared to do well. The Germans seemed to be bent upon heroic treatment in conditions in which we would employ milder measures; on the other hand their conservatism in the inflammatory cases exceeded ours. When their results were published we should be able to formulate a course of action by comparing their results with those of surgical methods.

Cesarean Section Demonstrated by Motion Pictures.—Dr. John Van Doren Young gave this demonstration. He pointed out the advantage of having a reel of this kind so that when one had a cesarean section to perform he could have the reel run off and thus refresh his memory. By noting faults in the technique he could avoid them. The motion picture reel was a wonderful analyzer of one's surgery. The operating time in the cesarean section was twenty-nine minutes. Dr. Young called attention to the advantages of the oil pad for walling off the uterus. It was easily introduced and easily removed without the gut following it; it left no peritoneal trauma and it absorbed perfectly anything with which it came in contact.

Dr. Bailey, commenting on the fact that argyrol was used in the eyes of this cesarean baby, said that both in Bellevue and at the Manhattan Maternity Hospital they used argyrol in the babies' eyes as a routine procedure, whether the child was born by way of the natural birth canal or by cesarean section. He thought there was no disadvantage in using argyrol in the baby's eyes after cesarean section.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Medical Examiners of Wyoming.

Cheyenne, June 6-8, 1921.

(*Continued from page* 43.)

PRACTICE.

1. Give cause of benign endocarditis. (*b*) Also cause of malignant endocarditis.
2. Give symptoms of malignant endocarditis.
3. Give cause and symptoms of dilatation of the heart. (*b*) What do you mean by relative insufficiency?
4. Give the cause, theory, and symptoms of chlorosis.
5. Give the causes, symptoms, and treatment of myxedema.
6. Give incubation period of smallpox, scarlet fever, measles, German measles, and whooping cough. (*b*) Differentiate between the pock of smallpox and that of chickenpox.
7. Give causes, symptoms, and treatment of uremia.
8. Give the causes of renal calculi, symptoms, and treatment.
9. Differentiate between general miliary tuberculosis and typhoid fever.
10. Give etiology, symptoms, and treatment of arteritis deformans.
11. Give period of eruption of enteric fever, typhus fever, variola, varicella, erysipelas, scarlet fever, measles, and German measles.
12. Give symptoms, diagnosis, and medical treatment of intestinal obstruction.

ANSWERS.

PRACTICE

1. *Causes of benign endocarditis:*—It is probably secondary to some infection, rheumatism, chorea, tonsillitis, scarlet fever, pneumonia, phthisis; it may be a terminal condition in cancer, gout, nephritis, or diabetes.

Causes of malignant endocarditis:—It is generally secondary to a previous endocarditis, or it follows a septic focus, as in pneumonia, osteomyelitis, otitis media, puerperal septicemia. (From Tidy's *Synopsis of Medicine.*)

2. Symptoms of malignant endocarditis. "Three types may be distinguished— (1) *The Septic Type* is characterised by the symptoms of septic infection—viz., rigors, sweats, oscillating temperature, emaciation, and metastatic abscesses. The symptoms may continue for months. (2) *The Typhoid Type* is characterised by irregular or intermittent fever, looseness of the bowels, petechial rashes, and a rapid assumption of the typhoid state. Great difficulty may be experienced in distinguishing this form from typhoid fever or meningitis. (3) *The Cardiac Type* is that in which symptoms of acute endocarditis, with fever of a septic type, appear in the course of a chronic valvular lesion. In some of these cases death is rapid; others may recover after a protracted illness.

"Along with these general symptoms there are usually definite cardiac signs—development of murmur, dilatation of the heart, cardiac irregularity, and so on. But the cardiac symptoms may be altogether latent, causing difficulty in diagnosis. Enteric fever and miliary tuberculosis are the chief sources of confusion. In malignant endocarditis there is leucocytosis, in enteric leucopenia; in endocarditis the murmur may change its character, or fresh murmurs may appear. In enteric the Widal reaction is present; in endocarditis blood-culture may show the presence of an organism. In miliary tuberculosis tubercle may be present in other regions of the body, and pulmonary signs are often marked.

In both simple and malignant endocarditis vegetations may be detached from the affected valve, and plug the smaller arteries. In the simple form these *emboli* are of importance when they implicate end-arteries (brain, lungs, kidneys, spleen), and they then result in hemiplegia, hæmorrhagic infarction of the lungs,

hæmaturia, and so on. In the malignant form the same results are produced when end-arteries are affected, but an abscess subsequently forms at the seat of the embolus, while in the case of other arteries metastatic abscesses ensue. Obviously the risk of detachment is greater in the ulcerative type."—(Wheeler and Jack's *Handbook of Medicine.*)

3. DILATATION OF THE HEART. *Causes:*—"This condition may be primary or secondary. It is *primary* when it is due to causes directly affecting the myocardium, such as bacterial toxins or chemical poisons, of which alcohol and tobacco are the chief examples, and when it follows emotion, shock, or physical overstrain. *Secondary* dilatation is the result of valvular lesions, adherent pericardium, increased peripheral resistance (arterio-sclerosis, Bright's disease), disease of the coronary arteries, and persistent tachycardia. Fatty and fibroid degeneration of the cardiac muscles predispose to it, and so does inadequate nutrition of the muscles, such as it met with in anæmia. Prolonged pyrexia may also cause it.

Symptoms:—See above. PHYSICAL DIAGNOSIS. 1. *Relative Insufficiency.* By this is meant that the cardiac valves are normal, but that the ring to which the valve segments are attached have become dilated or stretched and therefore the valve segments can not meet.

4. CHLOROSIS. *Cause and theories:* "The cause of chlorosis is unknown, though there are many theoretical explanations, of which the following are the chief: (1) The disease is due to constipation and toxic absorption from the bowel (Sir Andrew Clark). (2) The demands of puberty reveal a congenital narrowness of the arterial system, which prevents a proper supply of blood to the various tissues (Virchow). (3) The organic iron compounds of the food are broken up by excessive decomposition in the alimentary canal, and the iron thus liberated cannot be absorbed into the blood (Bunge). (4) Chlorosis is due to excessive loss of blood at the period of puberty (menorrhagia), which leads to dyspeptic conditions, anorexia, and defective absorption of iron (Stockman). (5) The disease is due not to an absolute diminution of hæmoglobin, but to an excess of plasms (Haldane and Lorrain Smith). None of these theories covers all the cases. Constipated subjects are not always chlorotic, there may be no congenital arterial defect or excessive loss of blood, and reduction of the plasma does not cure without administration of iron. At present we can only assume that in women the adolescent period causes an increased demand upon the blood-forming organs, which in some cases they are unable to meet. Predisposing causes are defective nourishment and want of fresh air and exercise. The disease is common in girls coming from the country to domestic service or to factory life; but it is met with in all classes."

Symptoms:—"Languor, dyspnœa, palpitation on exertion, headache, noises in the ears, and dyspeptic symptoms, as in symptomatic anæmia. The greenish waxy pallor of the complexion is conspicuous, but may be masked by ruddiness of the cheeks. The mucous membranes are pale. The more characteristic symptoms in addition are plumpness; systolic murmurs at the base of the heart; "*bruit de diable*" at the lower end of the jugular vein; constipation and irregular, profuse, or scanty menstruation. Mitral regurgitation is sometimes present—the result of relative insufficiency of the valve, following upon dilatation. Thrombosis of the femoral vein, or even of the cerebral sinuses, is an occasional complication, and gastric ulcer is not uncommon.

"*The blood* is pale, and the corpuscles are poorly colored. Poikilocytosis is sometimes present, and normoblasts may be found in severe cases. The number of red corpuscles is not greatly diminished (60-80 per cent), but the percentage of hæmoglobin is much below normal (30-50 per cent). The color index is thus fractional. Leucocytes are not increased."—(Wheeler and Jack's *Handbook of Medicine.*)

5. MYXEDEMA. *Causes:*—"The causes of the atrophy of the thyroid gland is unknown. It is more frequent in women than in men and usually develops about middle life. The disease is said to have followed the extirpation of the gland in the adult.

Symptoms:—The disease develops slowly, often a number of years elapsing before all the characteristic phenomena are present. The face and neck, and often other parts of the body, have a bloated appearance. The normal wrinkles are obliterated, the nose is wide and thick, the lips thick and everted, the mouth enlarged, as is also the tongue, giving a coarse and broadened or mask-like appearance to the features. The skin is denser and does not pit on pressure, but is pale or chalk-like, or yellowish white, with often a small reddish patch on either cheek. The expression of the countenance is immobile and stupid. The hands and feet are enlarged, the skin is coarse and dry. The shape of the hands is changed, presenting a "spade-like" appearance. The mental condition is sluggish and stupid, with loss of memory and of interest in the environments and affairs of life. Occasionally hallucinations of sight occur. The tendency is toward a dementia. Patients often complain of neuralgic pains and numbness and a sense of muscular weakness. The temperature is always below the normal. Anemia develops and often a subacute nephritis or a glycosuria or phthisis follows.

Treatment:—"The body surface should be protected from cold by warm clothing. Warm bathing followed by inunctions of olive oil is also beneficial. Warm climates are best adapted for these patients. The administration of thyroid extract, beginning with half a grain after meals, gradually increasing the dose until several grains are taken daily or until symptoms of thyroidism appear, is of great value. The remedy should be continued over a long period and withheld when evidences of thyroidism such as nervousness, restlessness, insomnia, dyspnea, rapid pulse, cardiac palpitation, gastrointestinal disorders, confusion of mind, or delirium become manifest. The anemia and muscular weakness are overcome by the use of iron, strychnine arsenite, gr. 1/60, and nuclein."—(Hughes' *Practice of Medicine.*)

6. The *incubation period of smallpox* is about nine to fifteen days, generally twelve; *of scarlet fever,* about two to seven days; *of measles,* about seven to seventeen days; *of German measles,* fourteen days or more; *of whooping cough,* about seven to ten days.

Smallpox: The eruption usually appears first on the forehead and wrists, and on the third or fourth day; it is first macular, then papular, then vesicular, and finally pustular; it does not appear in successive crops; the spots are multilocular, and do not collapse on being punctured; the papule is hard and shotty, and does not disappear on stretching the skin.

Chickenpox: The eruption usually appears first on the trunk, is evident on the first day, comes in successive crops, it not shotty, and disappears on stretching the skin; the spots are unilocular, and collapse on being punctured.

7. *Uremia.* "*Theories of origin:*—(1) Accumulation in blood of substances normally excreted by kidneys. In uremia, urea in blood may rise from 0.015 to 0.5 per cent (in eclampsia not above 0.05 per cent.). *Objections.*—(*a*) Suppression results in latent, but not acute or chronic, uremia; (*b*) Urea and other known substances in urine do not experimentally produce uremia. (2) Decomposition in body of such substances, forming toxic products. (3) Abnormal products from disturbed renal metabolism. Bradford showed that destruction of renal tissue results in increased excretion of urine with rapid protein metabolism. Possibly absence of an internal secretion of kidney. (4) Localized edema of brain. Could not account for all symptoms.

SUMMARY OF SYMPTOMS IN ACUTE UREMIA:—*Early stage.* Headache; sleeplessness; nausea and vomiting; tingling of fingers; slight twitching of muscles; cramps in calves; breath heavy; tongue furred; pupils contracted. *Progressing.* Severe vomiting; paroxysmal dyspnea; various paralyses. *Late stage.* Cheyne-Stokes breathing; epileptiform convulsions; death in coma. TREATMENT. *Chronic uremia and early symptoms:*—Induce sweating by hot-air baths or pack and pilocarpine; saline purgatives; nitroglycerin to reduce blood-pressure. Opium is a valuable and safe drug; useful for restlessness, insomnia, delirium; also for dyspnea and Cheyne-Stokes breathing; useful also after fits to ward off recurrence. *Coma.*—Induce sweating; open bowels; venesection. *Convulsions.*—Induce sweat-

ing; chloroform if fits severe; venesection; inject morphine if fits recur; other sedatives of little avail. With venesection, intravenous or subcutaneous infusion of sterile physiological saline solution or transfusion of blood. Continuous inhalation of oxygen may be useful. Lumbar puncture has been recommended."—(Tidy's *Synopsis of Medicine.*)

8. RENAL CALCULUS. *Etiology:* AGE.—Found at all ages. Clinically very rare below ten years; common between twenty and fifty. SEX.—Slight preponderance of males. HEREDITY.—In uric acid stone there is generally a well-marked family history. SIDE.—Right and left equally affected. HABITS.—Sedentary life and rich diet. WATER.—Lime in drinking water. CLIMATE. More frequent in hot countries, because evaporation and sweating concentrate the urine. INJURY.—May give rise to calculus round a blood-clot or first give symptoms by moving a calculus that has been present.

The *Symptoms* consist of pain in the loin, markedly increased by exercise, especially on jolting. The pain may be referred to the thigh, groin, or testicle. The colic is associated with hematuria, and often pyuria exists with frequency of micturition. The kidney may be enlarged, and tender on pressure. A large stone may exist without any symptom whatever.

The most typical symptom consists in a sudden attack of excruciating and paroxysmal pain shooting down the loin to the bladder and testis. The attack is accomplished by vomiting, faintness, and collapse. Frequent efforts to pass urine are made, but only a scanty amount of blood-stained urine is passed (strangury). The pain ceases suddenly when the calculus slips back into the pelvis or reaches the bladder.

Treatment—Palliative.—The patient's diet must be regulated so that there is no excess; plenty of fluid should be taken as well as proper exercise. Alkaline purgatives and urotropin should be ordered. Sometimes under this treatment a small stone becomes encysted, but it is unlikely that a stone once formed will be dissolved. Renal colic is treated by hot baths, ½ grain of morphia, or chloroform, to relieve the pain.

Operative treatment is adopted if the above means fail, if a perinephric abscess forms, or a stone is impacted in the ureter. Nephrolithotomy is the ideal operation, but if the kidney is converted into a mere abscess cavity nephrectomy is necessary. Nephrectomy should not be done if it is suspected that the other kidney is also affected. (*Aids to Surgery.*)

9. TYPHOID FEVER.	ACUTE MILIARY TUBERCULOSIS
1. History of an epidemic or of change of residence from the country to the city.	1. May be history of cough or of a tuberculous ulcer, abscess, fistula, etc.
2. Fever rises gradually, in step-like form, reaching its height in from seven to eight days, and declines during the third or fourth week.	2. Fever rises more abruptly, and remains high (continued type) until death.
3. Respirations are moderately increased, with few râles over the lungs.	3. Respirations from 40 to 60 a minute, with numerous crackling râles and at times increased respiratory murmurs over both lungs
4. Cough may develop early, but is mild, and usually abates during the second week of the fever.	4. Cough increases gradually throughout the disease, and there may be blood-streaked sputum.
5. Cyanosis is observed only late in the disease, when there is cardiac failure or pulmonary complications.	5. Cyanosis early.
6. Tenderness in the right iliac fossa. Tympanites and from two to six semi-liquid stools daily.	6. Constipation the rule.
7. Widal serum-reaction positive after the first week.	7. Serum-reaction negative.
8. Characteristic eruption appears over the abdomen about the end of the first week of the fever.	8. Eruption absent.
9. Cultures from the blood show the presence of typhoid bacilli in from 20 to 30 per cent. of all cases.	9. Culture may develop tubercle bacilli if proper culture-medium is employed.
10. Pupils are moderately dilated early during the course of the disease.	10. Pupils less likely to be dilated and tuberculous retinitis common.
11. Feces contain the bacillus of Eberth.	11. Tubercle bacilli often present in the feces.
12. Intestinal hemorrhage and intestinal perforation may complicate typhoid fever.	12. Intestinal hemorrhage and perforation absent.

—(Anders and Boston's *Medical Diagnosis.*)

10. ARTHRITIS DEFORMANS. *Etiology.*—Exposure to damp and cold is thought to have some influence. That it is of nervous origin is suggested by the similar condition developing in diabetes where peripheral neuritis is present, and that an exaggerated condition occurs in locomotor ataxia in the form of Charcot's disease. A bacterial origin is suggested, and also that it is of toxic origin. Some cases can be definitely traced to an injury, such as a sprain, fracture, or dislocation.

Symptoms of the common *chronic* type. This may be monarticular or polyarticular. The *monarticular* variety is often traceable to injury. Pain at the beginning of exercise and during damp weather, together with creaking on movement, and perhaps some effusion, constitute the symptoms. The cartilages are "lipped" in the later stages, and there are exacerbations of pain. The limb may become useless from the pain, limitation of movement, and wasting of the muscles. The *polyarticular* variety is not due to injury, and affects chiefly females in middle life. The interphalangeal joints are first affected, becoming swollen and stiff. Bony outgrowths occur around the joints. Other joints are affected, and the patient in time may be entirely crippled.

An *acute polyarticular* variety may occur in young people after some infective fever. The smaller joints are first affected, and there is accompanying pyrexia, anemia, and pigmentation of the skin, while the muscles are wasted, and neighboring lymphatic glands may be enlarged.

Treatment should aim at removing any source of septic absorption, such as pyorrhœa alveolaris, endometritis, urethritis, etc.; otherwise it is confined mainly to alleviation of the symptoms. The joints should be kept warm by flannel coverings, frequently massaged, and on no account must movement be limited by apparatus. Good feeding and a dry climate are necessary, while of drugs iodide of potassium is of the most use. When the disease is confined to one joint, and cripples the patient, excision may be advisable. In the hip-joint thickening of the trochanter and absorption of the head occur, so that the limb is shortened. If the patient falls upon the hip, some difficulty may be found in diagnosing it from fracture of the neck. The previous history, undue prominence of the trochanter, and normal rotation, distinguish it.—(*Aids to Surgery.*)

11. *Period of eruption, in enteric fever,* is about seventh to tenth day; *in typhus fever,* about third to fifth day; *in variola,* about the fourth day; *in varicella,* generally on the first day; *in erysipelas,* on the first day; *in scarlet fever,* on first or second day; *in measles,* about the fourth day; *in German measles,* about first or second day.

12. *Symptoms of acute intestinal obstruction:* "Sudden severe pain referred to the umbilicus comes on, perhaps, after an effort. Shock, evidenced by a weak pulse, a cold, clammy skin, and a subnormal temperature,

accompanies the pain. The pain, intermittent at first, becomes continuous. Vomiting is persistent, and soon becomes fecal smelling. The patient becomes exhausted by the vomiting and inability to take food. The abdomen becomes distended, and if the obstruction is not relieved, perforative peritonitis follows, so that the patient dies in about seven to ten days from the onset. Constipation is usually absolute, though the lower bowel may empty itself at first."

Diagnosis.—This is not difficult, but the cause can usually be made out only by opening the abdomen. The mechanical form of obstruction must be distinguished from the inflammatory form, especially that of appendicitis associated with peritonitis. The temperature, localized tenderness, and rigidity, of appendicitis serve to distinguish it.

Treatment.—"The only thing that can give the patient the chance he ought to have is immediate operation. It is advisable to wash out the stomach before the operation, so that intestinal contents may not be vomited and inhaled during the operation. Three objects are aimed at: (1) To empty the distended bowel above the obstruction; (2) to relieve the obstruction; (3) to treat the strangulated intestine. In cases that are almost moribund, the abdomen should be opened with cocaine or eucaine anesthesia; a distended coil is pulled out and tapped, a Paul's tube being subsequently tied in. The peritoneal cavity is protected with gauze packing during these manipulations. The bowel is stitched to the abdominal wound after the feces and flatus have drained away. No attempt at relief of the obstruction can be made in these cases till a later date, and, of course, a high death-rate must be expected.

In less severe cases the abdomen should be opened in the midline below the umbilicus, and a systematic search made for the cause of the obstruction. The hernial orifices are first examined, then the cecum. If the cecum is distended, the obstruction lies below it; if collapsed, above it. In the former case the sigmoid should not be examined. If collapsed, the colon must then be traced backwards till the obstruction is found. If the cecum is collapsed, the intestine must be pulled out a foot at a time and examined, beginning with the ileum, and replacing it as each part is done with. If the intestine is much distended, several coils may be tapped and emptied, to facilitate the search."—(*Aids to Surgery.*)

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

REPORT OF THE SURGOEN GENERAL, U. S. ARMY, 1921. 329 pages with illustrations. Published by the Government Printing Office, Washington, D. C.

GEBURTSHILFLICH-GYNÄKOLOGISCHE PROPÄDEUTIK. Third and 4th Editions. 195 pages with 96 illustrations. Published by Curt Kabitzsch, Leipzig.

PROSTITUTION U. TUBERKULOSE. By Dr. I. W. SAMSON. 120 pages. Price, 54 M. Published by Georg Thieme, Leipzig.

DOMICILIARY TREATMENT OF TUBERCULOSIS. By Dr. F. RUFENACHT WALTERS. 290 pages. Price, $4.00. Published by Wm. Wood & Company, New York.

THE ORGANS OF INTERNAL SECRETION. By Dr. I. G. COBB. 352 pages. Price, $3.50. Published by Wm. Wood & Company, New York.

X-RAYS AND RADIUM IN TREATMENT OF DISEASES OF THE SKIN. By Dr. GEORGE M. MACKEE. 602 pages with 250 engravings and 22 charts. Price, $9.00. Published by Lea & Febiger, Philadelphia.

DIE IMPOTENZ DES MANNES. By Dr. P. ORLOWSKI. 148 pages, 22 illustrations and 3 colored plates. Price 38 M. Published by Curt Kabitzsch, Leipzig.

BACTERIOLOGY. By Drs. E. D. and R. E. BUCHANAN. 360 pages with illustrations. Published by the Macmillan Company, New York.

Therapeutic Hints.

Seborrhea Oleosa.—Sabouraud advises the following application of sulphur, applied every night for men and once a week for women:

Camphorated spirit,
Tincture of lavender,
Precipitated sulphur.....of each 10
Distilled water .....to make 100

The lotion is painted on with a small camel's hair brush at night, and the head is washed thoroughly with soap the next morning. A tonic lotion is applied after this. An agreeable lotion recommended by Sabouraud is the following:

Tincture of lavender..... 20.
Anhydrous acetone ..... 30.
Distilled water..... 30.
Potassium nitrate 0.50
Alcohol (90 per cent).....to make 300.

This is rubbed in with a fairly stiff brush, the applications being made daily, if possible, and continued for ten minutes in the female and four minutes in the male.—*Journal des Praticiens.*

A Tooth Paste.—Alexander Lowy gives the following formula of a tooth paste to which he has given the name "F.E.I." (first eliminate infection):

	Per cent.
Precipitated chalk (body of paste, cleanser, antacid)	58.75
Glycerin (vehicle)	28.60
Water (vehicle)	5.60
Starch (binder)	1.10
Soap (cleanser, alkalizer)	5.00
Russian mineral oil (vehicle, lubricant)	0.25
Saccharin (corrective, antiseptic)	0.03
Emetine hydrochloride (endamebacide)	0.0015
Thymol (stimulant and antiseptic)	0.015
Menthol (stimulant and antiseptic)	0.3
Oil of eucalyptus (stimulant and antiseptic)	0.11
Methyl salicylate (stimulant and antiseptic)	0.11
Oil of peppermint (stimulant and antiseptic)	0.40
	99.9965

—*The Journal of Dental Research*, ii, 4.

Colic.—For an acute attack in children, ten to fifteen ounces of soap enema, injected slowly and steadily, will usually give prompt relief. Hot flannel fomentations to the abdomen, and a dose of castor oil if the usual cause is offending material in the bowel. If flatulence is the chief feature, give—

℞ Tincture of belladonna.....♏ ii
Aromatic spirit of ammonia.....♏ ii
Bicarbonate of soda.....gr. v
Peppermint water, to.....℥ i

M. Sig.: Every six hours for an infant of six months.—"Practical Prescribing and Treatment."

Weak Heart.—

℞ Tincture of strophanthus.....℥ss
Tincture of nux vomica.....℥ii
Compound spirit of ether.....℥iiss

M. Sig. Ten to 15 drops in water every 4 to 6 hours.

Medical History.

BOOK MAKING "THRU MILITARY CHANNELS."

"THE MEDICAL DEPARTMENT OF THE UNITED STATES ARMY IN THE WORLD WAR."

By LOY McAFEE, M.D.,

WASHINGTON, D. C.

ASSISTANT EDITOR-IN-CHIEF, "THE MEDICAL DEPARTMENT OF THE UNITED STATES ARMY IN THE WORLD WAR."

WHEN an advance copy of the first printed volume of "The Medical Department of the United States Army in the World War," familiarly known as the medical and surgical history of the war, was forwarded by the public printer to the Historical Division of the Surgeon General's office, just before the Christmas holidays, the members of the division could hardly determine whether they were the donors or recipients of a Christmas present. Whichever way the receipt of a copy of "Army Anthropology," which is Part 1 of Volume XV, on Statistics, might be interpreted, we heaved a sigh of relief as at last we could offer some tangible evidence of our labors. For the bringing out of a book or a series of books "thru military channels" is a far more complicated matter than is the accomplishment of the same feat in civil life. Because of these difficulties and differences it is believed that the readers of the MEDICAL RECORD may be interested in a sketch of the *modus operandi*.

When boxes and bundles of records began pouring into the Surgeon General's office from overseas and from the home territory toward the latter part of the war period, the historical division, then the historical section of the museum and library division of the Surgeon General's office, became one of the most active agencies in the office. A tentative outline of the proposed history, covering fifteen volumes, had been drawn up, and historiographers had been delegated for many of the subjects involved, men with first-hand knowledge of the events to be chronicled being selected insofar as this was possible. Demobilization had not begun, and the majority of the medical officers who were approached on the subject manifested interest and willingness to cooperate in the compilation of the permanent record of the part taken by the Medical Department of the Army in the war. One medical reserve officer, a member of the staff of the Historical Division at that time, talked quite enthusiastically and confidently of having the entire history on the bookshelves in a year and a half or three years, at most, from the armistice. Nobody actively connected with the Historical Division has been idle, and yet the end of the third year after the armistice finds one volume or book, which happens to be the first part of the last volume on the schedule, actually ready for distribution. Evidently haste, in the usual interpretation of the word, has been impossible. Why?

Congressional Appropriation Necessary.—Members of Uncle Sam's great establishment, from high executives to messenger boys, watch for the pronouncements of Congress with reference to appropriations for keeping the complicated machinery moving. The Historical Division of the Surgeon General's office was no exception to this rule. We might collect, analyze, and classify tons of historical records, but without the necessary appropriation by Congress everything would have to be marked "file," and then forgotten. For the appropriations for the Medical Department, "at large," or otherwise, were not available for use in printing and binding the history of the part played by this department in the war. Fortunately for the annals of military medical history, the Congress was not unmindful of the importance, not only to the Medical Department of the United States Army, but to the medical profession in general, of the printed and permanent record of the splendid achievements of the Medical Department in the greatest war the world has ever known. One may read, therefore, in the *Congressional Record* of June 1, 1920, the following:

> Conferee's report to the Senate, on the Sundry Civil bill, amendment No. 40, page 8695. The House recedes from its disagreement to the amendment of the Senate No. 40, and agrees to the same with an amendment as follows: In lieu of the matter inserted by said amendment, insert the following:
>
> "Medical and Surgical History of the War with Germany; toward the preparation for publication under the direction of the Secretary of War of a medical and surgical history of the war with Germany including printing and binding at the Government Printing Office and the necessary engravings and illustrations, $50,000; Provided that the total cost of such history shall not exceed $150,000, and the Senate agrees to the same."

Amendment No. 40 appropriated $50,000 instead of $75,000, as proposed by the Senate, and was agreed to by the Senate. The Historical Division, fortified by the approval of Congress, expressed in this appropriation, could proceed with renewed interest and determination.

Effect of Demobilization.—In the belief that an appropriation would be made in due time, the Surgeon General fostered the work on the history throughout the period of demobilization. The armistice, as all know, was followed by a rush for home by all medical reserve officers who could secure their discharge. Many of these men had first-hand knowledge of the actual events which were to be recorded in the history. Once discharged, they were no longer subject to command from the Surgeon General, and, while their interest in the history may have been no less keen, their desire to re-establish themselves in their respective civilian fields of activity was impelling. Furthermore, once out of the military atmosphere, and at a distance from the central machinery through which the history had to pass in the making, and from the mass of records which might or might not be useful in the given instances, but which should be examined, nevertheless, the delegated authors of sections, whether members of the Reserve Corps, discharged, or of the Regular Medical Corps, detailed to other duty, were seriously handicapped. Haste, under such circumstances, was and is virtually impossible. With the splendid cooperation of the temporary officers who, in the midst of their busy lives as civilian practitioners, have cheerfully responded to calls upon their time and thought, and with the help of the members of the Regular Medical Corps who, "in addition to their other duties," have rendered the assistance demanded of them, these difficulties are being overcome gradually, and with results favorable to the eventual satisfactory com-

pletion of the task, within a time limit which the circumstances warrant calling reasonable.

The Historical Division, as well as the Surgeon General's office and the Medical Department as a whole, experienced difficulties incident to demobilization and change of station or duty. The historical administrative machinery was set in motion in August, 1917, by War Department Special Orders No. 196:

> A board to consist of Colonel Champe C. McCulloch, Jr., M.C., and Major Fielding H. Garrison, M.R.C., is appointed to meet in this city for the purpose of collecting and preparing material for a medical and surgical history of American participation in the present European war. The officers named will perform this duty in addition to their other duties.

By another paragraph of the same orders Captain John S. Fulton, M.R.C., was made a member of the board.

Colonel McCulloch, then librarian of the Surgeon General's library, was the first executive officer of the board. He was succeeded by Col. Paul F. Straub, M.C., who was followed by Col. Francis A. Winter, M.C. With the reorganization of the Surgeon General's office which followed the armistice, the Historical Board, which had become the Historical Section of the Museum and Library Division, became the Historical Division of the Surgeon General's office, and was thus completely separated from the Museum and Library Division. Major Garrison (now lieutenant-colonel in the Regular Medical Corps) has continued in active connection with the history work, first as a member of the staff of the division, and later as a member of the editorial board, the advisory board of the Historical Division. Captain, later Lieutenant-Colonel Fulton, returned to civil life after the armistice. Lieut.-Col. Casey A. Wood, M.R.C., who was actively connected with the board, and later with the division, also returned to civil life, retaining his connection with the history as a member of the editorial board. In August, 1919, Col. Charles Lynch, M.C., was made editor-in-chief of the history, and executive officer of the division, in which capacities he continues to serve. The majority of the chiefs of the various divisions of the Surgeon General's office, who, by virtue of this position, were largely concerned with the initial work connected with the part of the history represented by the particular division, have been demobilized or detailed to other duties.

This necessary shifting of the military personnel has not tended to heighten the continuity of effort, or to lighten the task of the Historical Division. Finally, however, the division reached an "even keel," with the following editorial personnel: Col. Charles Lynch, M.C., editor-in-chief; Loy McAfee, M.D. (formerly contact surgeon, U. S. Army), assistant editor-in-chief; Col. Joseph H. Ford, M.C.; Lieut.-Col. Frank W. Weed, M.C.; Lieut.-Col. Samuel J. Morris, M.C.; Second Lieut. Frank J. Steiner, Medical Administrative Corps, and Mary Pearson McKnight, Contract Surgeon, U. S. Army. The remaining personnel of the division consists of two draughtsmen and ten clerical and other assistants. The editorial board, as at present constituted, includes the following members, in addition to the editor-in-chief and the assistant editor-in-chief:* Col. Bailey K. Ashford, M.C.; Col. Frank Billings, M.C.; Col. Thomas R. Boggs, M.C.; Col. George E. Brewer, M.C.; Col. Roger Brooke, M.C.; Col. W. P. Chamberlain, M.C.; Col. C. F. Craig, M.C.; Col. Haven Emerson, M.C.; Brig.-Gen. John M. T. Finney, M.D.; Col. J. H. Ford, M.C.; Lieut.-Col. Fielding H. Garrison, M.C.; Col. H. L. Gilchrist, M.C.; Brig.-Gen. Jefferson Kean, M.D.; Lieut.-Col. A. G. Love, M.C.; Col. James F. McKernon, M.C.; Col. C. F. Morse, M.C.; Col. R. T. Oliver, D.C.; Col. Charles R. Reynolds, M.C.; Col. Thomas W. Salmon, M.C.; Lieut.-Col. G. E. de Schweinitz, M.C.; Col. J. F. Siler, M.C.; Brig.-Gen. W. S. Thayer, M.D.; Col. A. D. Tuttle, M.C.; Col. William H. Welch, M.C.; Col. E. P. Wolfe, M.C.; Lieut.-Col. Casey A. Wood, M.C.; Col. Hans Zinsser, M.C.

Requirements of the General Staff.—In January, 1918, Gen. Tasker H. Bliss, the chief of staff, recommended the establishment within the War Department of an office which should devote its activities to military historical matters. Shortly thereafter an officer was detailed as chief of the Historical Section of the War Plans Branch of the War College Division, General Staff. In June, 1919, this organization became the Historical Branch of the War Plans Division, General Staff. By a further reorganization, in August, 1921, the office became the Historical Section, the Army War College, as which it continues to function.

In addition to its duties in the collection of historical data and in the framing of the outline of a proposed history of the participation of the United States in the World War, the task of passing upon all War Department histories was imposed upon the Historical Section (then Historical Branch) by the following communication, given in part:

April 5, 1920.

From: The Adjutant General of the Army.
To: The Chiefs of all Staff Bureaus, and Chief, Historical Branch, War Plans Division.
Subject: Unification of historical publications.

In order that historical publications prepared by the several services, departments and corps may be unified and fit into some general scheme, and to prevent duplication and to assure that the important activities of every service during the World War are made of record, the following general plan of historical publication is announced.

General Plan
for
All Services, Departments and Corps
of the War Department
For the Preparation of Historical Publications.

1. *Basic Principles of Plan.* All historical publications will be supervised by the Historical Branch, War Plans Division, General Staff.

Publications prepared by the services will be, first, those of a general character, giving an outline of a service with all its activities. Following these will be more specific papers dealing with particular activities, giving detailed information on a subject only generally referred to in the previous paper. This will insure a progressive program and one making information available in the quickest time and following a natural and logical order.

Historical publications relating to the technical activities of a service from the point of view of the service itself will be prepared by the Service Historical Officer [the Editor-in-Chief in the case in point]. The Historical Branch, in such cases, will be concerned only with the selection of supporting documents and the

*The highest rank held during the World War is used.

form in which the necessary references to such documents appear.

Historical publications relating to activities of services in broader aspects, from an outside point of view, will be prepared by the Service Historical Officer assisted by the Historical Branch.

Historical publications relating to military operations, or the activities back of the lines as affecting such operations, when two or more services are concerned, will be prepared by the Historical Branch, War Plans Division, General Staff, assisted by the Historical Officers of the services concerned.

. . . . . .

3. *Conferences of Service Historical Officers.* After the designation of Service Historical Officers conferences will be held at such time as may hereafter be designated by the Historical Branch, War Plans Division, General Staff. At these conferences the policies and requirements of each service in the matter of historical publications will be presented and a special plan drawn up giving a detailed plan of publication for each service.

4. *Classification of Documents.* Documents in the possession of the various services will be classified as administrative and historical. The former class consists of those that are necessary, or may hereafter become necessary in the administration of the service. The latter class consists of those documents that were originally prepared for historical purposes, or documents originally administrative, which are no longer in use as such. Technical documents will be classified as administrative. If practicable these two classes of documents should be separated; but in any case the Historical Officer should familiarize himself with all historical documents of his service.

. . . . . .

7. *Form of Publication.* To insure accuracy all publications will be based upon existing primary documents when practicable. That this care in the preparation of work has been taken should be made evident on the face of the publication itself by attaching to each paper prepared a list of documents constituting sources consulted and giving the location and brief description of these documents; and to facilitate further study of the subject, references should appear in the body of the work to the particular documents of the source list relied upon as a basis for every important statement of fact or conclusion.

By order of the Secretary of War:

(Signed) H. G. Learnard,
Adjutant General.

From this it is seen that the history of the Medical Department, like that of all other War Department bureaus, must be submitted to the Historical Section of the General Staff, and that it must conform to the general requirements, of which No. 7, "Form of Publication," is the most important, and the one which sounded the death-knell of the "Hurry Up Squad."

The words, "primary documents," sound simple enough. In a civilian publication the task imposed by the order to give primary documentary proof of statements made would be easy enough of execution. In medical literature, to be sure, it would prevent the fault into which so many doctors have fallen, of quoting Dr. Jones as having said that Dr. Brown stated that Dr. Smith related that Dr. White reported so-and-so. And to that extent it would certainly make for accuracy, as it does in the military field. The task which this order imposes upon the Historical Division of the Surgeon General's office, however, is far more complicated than anything known in civil life. "Primary documents," from the military point of view (and it must be borne in mind that the medical and surgical history of the war is a military history), are actual official documents, cablegrams, telegrams, office orders (of a given bureau), memoranda, circular letters, War Department general orders and bulletins—in short, any kind of pronouncement of the given War Department bureau (the Medical Department, in the present instance), or of the War Department itself, as well as of other branches of the Government, should these be involved.

When one realizes that the mail and record section of the Administrative Division of the Surgeon General's office, at the peak of the war activity, received, recorded, and filed 177,396 pieces of primary documentary evidence in a single month, one can form some faint idea of the task which confronted the Historical Division when the full import of documentation became clear.

With the professional or technical volumes of the history the documentation is not so extensive as it is with the purely administrative volumes. The Historical Section of the General Staff, furthermore, assumes no jurisdiction over professional matter, further than to see that it conforms to general military usage. "Army Anthropology," with 574 pages of text, has twenty-five references, with five "additional authorities consulted." Most of these references are bibliographic, hence easily obtainable from a library, if not given by the authors. On the other hand, a short section of the administrative history—the history of a division of the Surgeon General's office, for example—may have a hundred or more references, each citing an official paper which started or was otherwise concerned in the given part of the administrative machinery, and which must be located and properly designated in reference form.

Each official paper thus cited serves as a check on the statements made by those who compile the history, and therefore makes for accuracy of detail. Furthermore, the citations make it possible, in the future, for one to find the original documents, should this be desirable for any reason.

No formal orders have been issued regarding certain other requirements of the General Staff, some of which have long applied to military publications, while others have become familiar to the Historical Division of the Surgeon General's office through correspondence or personal contact with the Historical Section of the General Staff.

For purposes of convenience the requirements of the General Staff, together with our own requirements with reference to the set-up of the references and other details, have been formulated by the Historical Division in the following sequence, mimeographed copies of which are available as needed:

1. *Primary documentary evidence* must be used.
2. *Secondary documentary evidence* may be used only when primary cannot be obtained.
3. Every *basic statement* must be substantiated by documentary evidence.
4. Only *historical facts* capable of documentary proof, or facts established by "common knowledge," are to be used.
5. *Personal opinions* (of the historiographer) are not permissible. Opinions of observers, official or otherwise, must be documented.
6. *Criticisms*, as such, are not permissible. If the matter under discussion warrants criticism, the criticism must be stated as historical fact, capable of documentation. For example, the *results* of errors in judgment may be stated as facts; the fact that an error in judgment was made need not be stated—this is left for the reader to deduce. It is not for the military historian

"to fix blame or bestow praise." Neither can be documented.

7. Names and personal statements not permissible unless necessary for purposes of accuracy and clarity, and capable of documentation. "If the name embellishes the history, it may be used; if the history embellishes the name, it must be omitted."

8. A complete reference gives (1) the *document;* (2) the *date;* (3) the *place* of filing.

The *document* must be clearly identified. If a letter, the "to," "from," and "subject" must be stated. If a book, or one volume or article in a "series," the full title, the author, the publisher, the place of publication, must be given, in addition to date, volume, and page, if required. If a magazine article, the title, name of journal in which published, place of publication, year, volume, number, and page. Government publications are to be identified with equal clearness. For example, "Surgeon General's Report" does not answer for "Report of the Surgeon General, U. S. Army."

The *date* includes day, month, year of correspondence; year, volume, number, or month or month and day for monthly and weekly publications; year for books and series of books, in addition to volume and page, if required.

The *place* applies to documents filed, not to books, magazines and non-official publications. As: "On file, Record Room, S. G. O., 024.-13 (Medical Record Division)."

Requirements of the Office of the Secretary of War.—There is in the office of the Secretary of War an important organization known as the Division of Printing and Advertising, which is under the direction of the assistant and chief clerk, War Department, and which has charge of all matters relating to printing and binding and advertising for the War Department and the Army. The Division of Printing and Advertising is likewise the medium of transmission for all communications with the Joint Committee on Printing, Congress of the United States, and the Public Printer upon all matters pertaining to the public printing and binding for the War Department and the Army. This office issues requisitions for printing, without which not even a line of type may be set by the Government Printing Office. And such requisitions for printing will not be issued without the approval of the proper authority. In the case of the medical and surgical history of the war, approval, as we have seen, must be obtained from the Historical Section of the General Staff. Each volume of the history, therefore, in its peregrinations from the editorial office to the bookshelf, must go to the Historical Section, General Staff, for approval; to the Surgeon General's office for the necessary request to the Division of Printing and Advertising of the Office of the Secretary of War; to the Division of Printing and Advertising for a requisition for the printing, illustrating, and binding by the Government Printing Office; and, finally, to the great printshop for formal "jacketing" or entry, and printing.

Requirements of the Government Printing Office.—When the Historical Division reached the point of considering the necessary mechanical details involved, such as type display, it was decided to select sample pages of material already formulated which would show the various styles of matter—solid reading matter, quotations, simple tabulations, complicated and lengthy tables, and matter which would account for at least six different values of headings and sub-headings—and to have these printed in the different types selected. It proved to be no easy matter to select the various types to meet the possible requirements of fifteen volumes, with their one or more parts, covering such a diversity of subjects. When this was finally accomplished, we became aware that it was impossible to have these few sample pages set up without a requisition. It was not necessary, in this instance, to secure the approval of the Historical Division of the General Staff, but all the other steps enumerated above had to be taken before this small amount of printing could be secured. Incidentally, it may be stated, these sample pages of type display were formally approved, as showing the type to be used, by the editorial board, and have been very useful in preparing the manuscript for the printer. For, with the Government Printing Office, more than with private printing establishments, nothing must be left to the imagination of the linotype operator.

With the enormous volume of printing turned out by the big establishment, with day and night shifts of workers, and with the close division of labor, a given job goes through too many hands for the personal-interest element to follow a piece of work from start to finish, as is sometimes possible in other printing places. This may be appreciated when one recalls that the Public Printer, in his recent annual report, estimated that if the paper used by the Government Printing Office during the year were laid flat at a thickness of one sheet it would cover approximately thirty-five square miles, and that if made into octavo books piled one on the other, they would extend five hundred miles into the air. During the fiscal year ending last June 30, 50,000,000 pounds of paper were used for printing and binding, and the total expenditures of the office were $11,111,111. It is easy to see, therefore, that no essential detail may be left unaccounted for or to be taken care of "from memory." Once all these preliminary requirements have been met, proof begins to come fairly promptly and evenly, until the given job is completed.

Present Status of the History.—As previously stated, the original outline of the history provided for fifteen volumes, and this number has been adhered to, being sufficient to cover the major subjects. As the work has progressed, however, it has been found that the material is too extensive to be condensed into fifteen volumes, and that in some instances it will be necessary to divide a given subject into one or more parts, each forming a separate book. On this basis it is believed that the history, as finally completed, will consist of fifteen volumes, totaling twenty separate books, or parts. The arrangement of volumes and parts thereof, subject to minor changes, is as follows: Volume I, Central Administration, United States; Volume II, Organization and Administration, A. E. F. (including hospitals); Volume III, Field Operations, A. E. F.; Volume IV, Sanitation (United States and A. E. F.); Volume V, Finance and Supply (United States and A. E. F.); Volume VI, Hospitals, United States; Volume VII, Posts, Camps, and Ports; Volume VIII, Communicable and Other Diseases; Volume IX, Neuropsychiatry; Volume X, Surgery: Part One, General Surgery; Part Two, Empyema; Part Three, Neurological Surgery; Part Four, Maxillo-Facial Surgery, and Ophthalmology; Part Five, Otolaryngology, Roentgenology, and Orthopedic Surgery; Volume XI, Physical Reconstruc-

tion; Volume XII, Education and Training; Volume XIII, Gas Poisoning; Volume XIV, Dental Corps, Veterinary Corps, Army Nurse Corps, and Air Service Medical; Volume XV, Statistics: Part One, Army Anthropology; Part Two, Medical Statistics.

It is proposed to publish these volumes or parts as they are ready for the printer, irrespectve of volume sequence. Thus the first to appear is Part One of Volume XV. Others will appear as rapidly as the circumstances detailed above will permit.

ARMY MEDICAL SCHOOL.

Seven Centuries of Medicine and Surgery in Montpellier.—On the occasion of the celebration of the seventh centenary of the University of Montpellier, Professor Vires reviewed the history of its medical work, beginning his résumé with the reorganization of medical teaching in the ancient city through a bull by Cardinal Conrad in August, 1220. Christians, Arabians, and Jews were united in the new Faculty. No one knows when medical instruction first commenced but the city itself dates from the VIII century. It was a midpoint between Spain and Italy. There were rabbinistic schools of medicine in some of the Languedoc cities during the IX century, and Spanish Arabs were at a later epoch diffusing the teachings of Avicenna in France. But the Salernitan School in Italy is known to have attracted to it the Christian students of Montpellier at the close of the IX century. It is probable that these men after their return from Salerno laid the foundations of medical teaching in their home city, where they had to compete with the Judæo-Arabs. We are now in position to understand why a consolidation of these factions eventually became advisable in order to found a democratic medical institution. The speaker did not allude to the first three centuries of the new institution, but sketched a picture of it in 1536. The faculty presented a galaxy of great names remembered chiefly today for their botanical and zoological attainments. Most of the socalled "fathers of botany" were alumni of Montpellier. But there was no Botanical Garden in the town until 1593. The great Rabelais next appears on the scene, and all in all he is the most illustrious alumnus.

Professor Forgue gave a résumé of surgical teaching in the faculty. The barber-surgeon guild claimed to have originated in 1098 and classical surgery was first taught in the XII century, in advance of the formation of the University. In 1376 the Pope suspended the teaching of surgery in the latter, so that the master surgeons were for years extramural, but the physicians were allowed to dissect the bodies of condemned criminals. Singular is the omission by both Vires and Fargue of the activities of Bernard Gordon, who put Montpellier on the medical map in the XIII century, but who probably had no affiliation with the medical faculty of the college.

Professor Delmas of the Faculty cites a similar address given by Professor Ranchini, the chancellor of the same body, about 300 years ago, in which he said poetically that Apollo himself, God of Medicine, had retired to the beautiful Narbonnaise city after his mythological activities were over and had presumably inspired the foundation of the medical school. Delmas comments that not Apollo but Mercury, God of Business Men, should have been the deity to settle this vicinity with its strategic situation for commerce. In 737 Charles Martel, having been compelled to destroy the city of Magdelone, erected Montpellier on its ruins as a center for Mediterranean trade. In the tenth century its inhabitants comprised Jews from Spain, Arabs from Africa and Christians from Italy. Some of these aliens were scholars who acted as a leaven upon the ignorance and superstition of the masses. About the year 1000 some of these scholars had a title of "magistri physici." About a century later St. Bernard complimented the city on its learning. While there was no organized medical instruction at this period there was certainly private teaching which culminated in rivalry, certain individuals claiming to be the sole authorized to teach and demanding legal prohibition of others as outsiders. But Guilhem VIII promptly squelched these pretenders and pronounced the field open to all alike. This was in January, 1181. The city had been pontifical land since 1085, but the Church did not establish the medical faculty until 1220. It might not have come to pass then had not the legate Conrad visited the city on business connected with the Albigenses. The conditions which culminated in the creation of the faculty had been serious and had in fact been accumulated for 40 years. As noted above, the creation of the Faculty involved treating the Jewish, Mohammedan, and Christian factions equally, the membership having been divided among the three religions, a liberal policy hardly conceivable at that period.

Meglin and His Pills.—Meglin of pill fame passes in encyclopedic biographies as a fortunate individual, because he is generally ignored altogether, and presumably led an uneventful and therefore happy life. About all that is known of him authentically is his birth in Alsace in 1756, that he succeeded as a medical practitioner in that province, that he analyzed some mineral waters, wrote a book on neuralgia, and died in 1824. But he was also a member of the *Athenée de Médecine de Paris*, and this argues some exceptional attributes. Dr. Leclerc has, therefore, been curious enough to do a little biographic research. He located the volume published by Meglin at Strasbourg in 1816 on facial neuralgia and tic douloureux, a study of which shows that the author was an excellent clinician and therapeutist. He was, moreover, a humanitarian, seeking the relief of mankind from the atrocious pains of tic douloureux. His pills for the latter consisted of equal parts of sublimed zinc oxide, extract of black henbane, and extract of wild valerian. Henbane, up to that time regarded as a useless poison, was first recommended by Storck in 1762, and valerian was employed by Italians as early as the seventeenth century. No one before Meglin had used these remedies for painful affections. Meglin wished to combine a tonic with a sedative action. The pills weighed a grain each, and, beginning with one morning and evening, were run gradually up to 20 a day. In simple and dignified language Meglin hoped that he had made a permanent contribution to the relief of intolerable human pain. History seems to have borne him out, for today his pills are in the French Codex practically unchanged.—*La Presse Médicale.*

THE MEDICAL TREATMENT OF HYPERTHYROIDISM.

BY S. P. BEEBE, Ph.D., M.D.,

NEW YORK.

THE trend of therapeutics in the last twenty years has been toward specific medication. The increased knowledge of disease and the vast improvement in available therapeutic agencies make such a result inevitable. This development is most marked in the treatment of the infections, and the very notable increase in the expectation of life and diminished mortality rates have been accomplished for the most part by the effective fight against the infections, but the result has been attained more through the methods of preventive medicine than by the improvements in treatment.

In many physical disorders we must deal with complicated conditions in which the direct effect of a single causative agent cannot be demonstrated. In such cases we must plan an entirely different type of campaign. Direct frontal attack with a high powered battery is so much more interesting than siege operations, or even a flanking movement in the presence of an elusive enemy. Surgical removal of the offending gland appears to be a direct specific therapeutic measure in the treatment of hyperthyroidism and has gained wide acceptance. In recent years radiotherapy has attacked the gland directly, and its advocates claim for it effectiveness without the danger attendant upon surgical removal. Both methods are direct assaults upon what seems to be from superficial observation the chief offending structure, but the writer believes they will not be finally established as the best methods for universal application to the syndrome recognized as hyperthyroidism. The technique of the operation has been developed wonderfully in ten years, but the crest of the wave of thyroid surgery has probably passed owing to the increased knowledge of the etiology and pathology of the disease which has complicated rather than simplified the problem. The proper treatment of hyperthyroidism is not entirely settled by surgical removal of a portion of the gland. Much of the benefit from operation is the result of the medical measures instituted before and following the operation, but it rarely happens that the surgeon is by training or experience a capable medical adviser.

During the last ten years medical treatment has improved also. Many suggestions of possible specific therapeutic agents have been made, but the difficulty is that specific methods regard only one phase of the disease. The medical men have not as a rule spoken with the directness that the surgeons have, and many of the books have an astonishing paucity of helpful, useful therapeutic information. For example, in the second edition of Falta's book on "The Ductless Glandular Diseases," forty-seven pages are devoted to a study of Basedow's disease and only four pages to prognosis and treatment, most of which is made up of quotations from other writers giving suggestions as to what might be expected from various types of medical and surgical methods.

Nevertheless, certain definite principles in the medical treatment of hyperthyroidism have been established. In dealing with thyroid disease we have a constitutional defect played upon by a variety of unfavorable conditions, and the medical treatment is a regimen carefully planned to remove all untoward stimuli, nervous, chemical, and toxic, which influence the gland's abnormal activity. Quite naturally the application of these principles to a particular patient calls for a complete study of the actual condition. Neither medical nor surgical treatment will go far toward affording relief unless it is based upon an intelligent analysis of the patient's condition.

Accepting for purposes of discussion Plummer's classification of goiter into three types, colloid, adenomatous, and exophthalmic, we find that the surgeon surrenders all claim to colloid goiter.

In his recent article Sistrunk from the Mayo clinic says: "Colloid goiter is the only type of goiter which disappears under the administration of iodine or thyroxin and should not be considered a surgical condition." This is a large concession, for this type of gland has been removed in large numbers in recent years, and it is a sharp contrast to deal with them solely by the simple administration of iodine. The medical treatment involves other factors than the giving of iodine, but there is evidenced in this statement a marked change in thought.

Our chief interest, however, is with those types classed by Plummer as adenomata and exophthalmic goiter, since in these groups we find the surgeon still maintains the dominant interest. Even in these groups, however, a somewhat more conservative tendency is showing itself. Speaking of the adenomatous goiters Sistrunk says: "Since it is known that these goiters do not produce toxic symptoms at the time of life when they usually develop and that the thyroid gland at that particular time of life is very essential, it seems best to defer operations in young persons." These are wise words and ought to be inscribed on the walls of every operating room. The tendency has been too strong to subject all goiters to operation at the earliest moment they

come for advice. Seen at the time described above, practically all of these patients can be treated successfully by medical measures and all necessity for considering operations at any time will be avoided. Additional experience with the different types of goiters has convinced many surgeons that immediate operation at first sight is not a defensible practice.

Medical treatment does not wait for favorable opportunity or selected cases. The physician cannot refuse his services because the patient is very sick. And the possibilities of medical treatment are now so definite and the relief is so pronounced, that when properly understood and applied by the profession only a small proportion of the patients will ever need to be operated upon. Medical treatment should be preventive as well as curative and the physician should regard every thyroid enlargement with grave concern until it is proven harmless, as the surgeon does every growth in the breast. It is no longer good practice to minimize a thyroid enlargement because the patient is seemingly in good health on cursory observation. Such advice is reprehensible, but it is frequently given.

For the purposes of medical treatment there is small distinction to be made between those types designated by Plummer as toxic adenomata and exophthalmic goiter. It is not the custom to remove a portion of the gland for microscopic section to make a diagnosis. The present writer does not agree with Plummer that these two conditions are radically different in their response to treatment, nor in the type of medical measures that should be employed in their relief.

From the pathological standpoint we recognize different types of kidney disease as: (1) Chronic parenchymatous nephritis, (2) Chronic diffuse nephritis, (3) Chronic interstitial nephritis, (4) Amyloid and fatty kidneys, but where is the clinician who will base his diagnosis and treatment upon these pathological conditions?

The types described by Plummer as adenoma and exophthalmic goiter are those which may be grouped together as toxic goiter. They are not sharply defined unless one chooses to pin the differentiation on one symptom, exophthalmos. From the standpoint of medical treatment they should be dealt with on certain general principles and not by administering one single drug, vaccine, or physical agency. There is no specific for the disease and never will be because its etiology is too complex. Proper treatment is a regime and not the administration of drugs alone. Experience alone enables one to estimate the relative weight of the varying factors in this regime, but if the preliminary physical examination has been sufficiently detailed it will go far beyond the mere determination that the patient has the four cardinal symptoms with an increased basal metabolism. The published reports of case histories giving results of treatment with a variety of agencies as a rule give none of the secondary facts regarding the patient's condition, and from the standpoint of intelligent treatment these are mighty important.

For example, in Means' report from the Massachusetts General Hospital we read the following case history:

> The next surgical case is that of Miss M. D. (Laboratory No. 125, Hospital No. 212,305). She was a woman of twenty-seven years whom I first saw in December, 1916. She had had symptoms of Graves' disease for a year and a half—extreme nervousness, pathologically large appetite, marked sweating, loss of thirty pounds within a year and considerable dyspnea on exertion. She had slight exophthalmos, a very well marked tremor of the fingers, hot moist hands, and a moderate hard symmetric enlargement of the thyroid over which was heard a loud bruit.
>
> A chart accompanying the report shows an increased basal metabolism with correspondingly high pulse rate. Before entering the hospital she had the right superior thyroid artery tied. On entering the hospital she was put to bed. Both pulse rate and basal metabolism dropped rapidly and during the next two months she had two further operations and one *x*-ray treatment. At the second operation the right lobe and isthmus were removed. Two years later the patient stated she felt well, had been working for two years. She had no clinical evidence of thyrotoxicosis, but her metabolism was still 23 per cent. above normal.

The case is cited to show how the secondary conditions are either overlooked or are considered of no value. I believe this is one reason why medical treatment fails so frequently to produce excellent results. In the case under discussion we know nothing of the possible focal infections in tonsils, teeth, cervix, nasal sinuses, etc. We know nothing of the gastrointestinal conditions and dietary habits that may be all important. Nothing is known regarding the emotional factors. In fact, except for the pulse rate and metabolism determination, we know nothing that may not be learned from a superficial, cursory examination. We are told enough indeed to give a name to the disease, and that can be done at a glance, but unless a more thorough study is made of all the factors underlying the condition the treatment will necessarily be unsatisfactory, and in the present instance except for the rest preceding the operation, treatment was confined to a direct assault on the gland. It is in fact a kind of therapeutic nihilism not justified by the nature of the disease itself, nor by the experience with adequate treatment.

It must be constantly emphasized that the first step in medical treatment is a careful study of the patient, not for the purpose of naming the disease, but to learn if possible what factors have been responsible for exciting an inherently unstable gland into an abnormal degree of activity. We rarely excise the stomach because it has a hyperacid secretion. We try to determine what factors are responsible for the increased activity and remove or correct them. So long as the treatment is confined to a direct assault on the gland by some destructive method it will naturally be unnecessary to make a further study of the patient than the cursory examination which discovers the presence of an enlarged gland with toxic symptoms; but if these patients are to be dealt with intelligently most careful search for all disturbing factors must be made. It may seem trite to continue emphasis on this point, but my experience in the last ten years demonstrates the contrary to be the case and the published reports in almost every instance point to the same fact. Careless examination and one-gun therapy are the common means of treating toxic goiter.

The proper medical treatment of toxic goiter requires observance of the following considerations:

1. Rest; physical, mental, and emotional.

2. Diet; rigid meat-free diet and exclusion of all forms of stimulants such as tea, coffee, and alcoholics.

3. Special study of the functions of the stomach and intestine to relieve intestinal stasis and toxemia.

4. Search for and elimination of all sources of focal and chronic infection.

5. The administration of iodine in small doses over long periods of time, the dose being adjusted to the conditions in each case.

The principles outlined above are fundamental in every case of toxic goiter. In many cases other factors enter and special measures must be applied, but in no case can there be neglect of any of the principles given here if really satisfactory results are to be obtained.

1. *Rest:* There is a unanimous opinion among both physicians and surgeons that hyperthyroid patients improve with rest. In fact some maintain that it is the only medical measure that has any influence in improving the patient's condition. Rest means more, however, than putting the patient to bed. Most cases show some improvement on going to bed, but this is not a constant quantity, and with some patients indeed the disease may be made worse if rest in bed is the only medical treatment. Mental worry and emotional shock must be considered also and the proper kind and amount of rest required cannot be determined unless the physician knows all the factors in the case. It may be necessary to get the patient out of her immediate environment, it may mean removal from a quarrelsome, nagging family circle, it may mean change in social habits or relief from self assumed responsibility. It may not be necessary to so far alarm the patient as to require continuous rest in bed, a method of treatment that cannot be the only measure employed for any extended period. In the last five years the writer has not found it necessary to confine a large percentage of these patients to continuous rest in bed.

For example, just now a young man twenty-five years of age presents himself for advice. He has a well marked exophthalmos, small, uniformly enlarged, hard, shotty thyroid, pronounced tremor, nervous, restless manner, pulse rate 120 with a pounding heart, throb in the cervical vessels, blood pressure 150, hot moist hands, very sensitive skin. He tires quickly and has marked dyspnea and cardiac distress on exertion. He has not slept well for weeks, has lost ten pounds in two weeks although still at work, poor appetite at present, gastric and abdominal distress. Tonsils were removed two years ago. His bowels move once daily, he drinks four to five cups of coffee daily and is a heavy meat eater. For some weeks he has not gone to bed until 12 M. to 1 A. M. He has been at work continuously since he left the army at the close of the war, during which he served without physical defect. He presents a typical picture of exophthalmic goiter, not of especially severe grade, although his history shows that his condition is rapidly getting worse.

How much and what kind of rest does he need? This question cannot be answered from the facts already given. He comes for advice not because he believes himself to be sick with a constitutional disease, but because he believes he has contracted syphilis following exposure four weeks previously. His present state of mind is one of intense worry and panic. He has walked the streets in terror, afraid to return home to his friends and fiancée. He has read much about syphilis in the last ten days, expecting daily the appearance of a rash and has imagined every small skin blemish to be its beginning.

In this case the mental worry has whipped a mild condition of hitherto unobserved exophthalmic goiter into an active state of toxemia. Examination reveals the fact that his fears are unfounded, he has no syphilis and that night he sleeps well for twelve hours. The burden has been removed. His further treatment will not now be discussed, but it follows the above outline. He does not need continuous rest in bed any more than he needs partial thyroidectomy or *x*-ray treatment. In fact to put him to bed continuously for any period would do harm because of the new worries it would cause.

Rest is not a panacea for toxic goiter. It is an essential part of the treatment but it must be adjusted to the patient.

2. *Diet:* Meat free diet, with exclusion of all forms of stimulants, tea, coffee and alcoholics, is necessary. In this regard all forms of flesh food, including fish and fowl, are classed as meat. In a later paper the scientific basis for this form of diet will be discussed, but two or three points of moment may be mentioned.

First.—In toxic goiter we are dealing with a metabolism already heightened abnormally, and the rich protein diet by reason of its specific dynamic action stimulates the oxidation to still greater heights.

Second.—The fundamental metabolism experiments have demonstrated beyond question that a diet rich in carbohydrate and fat is much more effective in protecting the protein of the patient's own tissues.

Third.—Watson's experiments in rats have demonstrated that on an exclusive meat diet the gland develops a decided hyperplasia, with a loss of stored up colloid, and marked evidences of hyperactivity.

Fourth.—Kendall's experiments with thyroxin show that, given alone, it causes no acceleration of the pulse rate, but when given with amino-acids there is marked acceleration. Amino-acids come from protein in the food supply.

Fifth.—The intestinal bacterial flora on a meat diet is widely different from that on a vegetable diet, and most of these patients have a disordered digestion with undue toxin absorption.

Sixth.—Clinical experience shows that the patient does badly on a meat diet. This is no new observation. The fundamental character of Graves' disease has not changed during the years since W. H. Thomson wrote: "Let a patient with a temporary improvement in the symptoms partake heartily of beef three times a day, particularly at night, and immediate relapse will occur. Every one of the characteristic disorders will be as surely aggravated as those of a diabetic upon a free indulgence in starches."

It is useless to give drugs, and various combina-

tions of ductless gland products, psychotherapy, rest, *x*-ray treatment, etc., unless this essential fundamental in treatment is observed, and the patient is put on a rigid meat-free and stimulant-free diet.

3. There must be special study of the functions of the stomach and intestine to relieve intestinal stasis and toxemia.

Much has been said of the intractable diarrhea in Graves' disease. This is not a common event, and is not as a rule difficult to control by treatment with proper diet, bismuth salts, and occasionally a mercurial laxative. A much more common condition is a state of intestinal stasis. With 90 per cent. of the patients that have come under my observation I have found it necessary and desirable to use laxatives to secure from 3 to 5 bowel movements each day. Two grains of calomel once each week followed by a saline is a frequent requirement. The relationship between intestinal toxemia and hyperthyroidism is a most important one. Many writers on the subject have emphasized this fact, but it has not become a part of the accepted medical practice to pay any especial attention to the matter unless an actual obstruction develops.

W. H. Thomson was a keen clinician and he was dealing with a large portion of the truth when he stated, "The proper medicinal treatment of Graves' disease affords one of the most conclusive proofs of the gastrointestinal origin of the malady."

In the cases which have continued in a chronic state for several years, with occasional exacerbations, it is especially necessary to pay very careful attention to the gastrointestinal tract. An *x*-ray examination may and frequently does reveal abnormalities that have been entirely overlooked.

4. There must be a search for all sources of focal and chronic infection and these must be eliminated. The thyroid gland is stimulated by the absorption of bacterial toxins. There is, in fact, much evidence to support the view that the thyroid secretion is one of the most important links in the chain which defends the body against infections.

The writer has repeatedly called attention to the close relation between infections in the nose and throat and the development of hyperthyroidism. The experiments of McCarrison are most conclusive on this point. He has administered bacterial toxins both by mouth and by stomach and finds an invariable response in the gland. The type of pathological changes is dependent upon the virulence and size of the dose and the nutrition of the animal. Certain quotations from his work are most apropos at this point.

"Small doses over long periods act as stimulants to the gland's secretory activity."

"Nutritional factors are of great importance in gauging the action of these toxic substances; what may be a minimum dose for a robust individual may be a maximum dose for an ill-nourished one."

"The changes in the quality and quantity of the thyroid's secretion in this disease are primarily the outcome of the toxic excitation of the gland itself and of the sympathetic nerves controlling its secretion."

The examination of the patient must include a careful and thorough search for infections in teeth, tonsils, adenoids, nasal sinuses, cervix uteri, appendix, gall-bladder, as well as the toxic processes of the intestinal tract. Cases are rare that do not show some infection in these areas and they are habitually overlooked. With respect to the tonsils and adenoids the recent employment of *x*-ray treatment as advocated by Witherbee is an advance of much importance as it enables us to eliminate the infection in these areas without the shock and danger of operation. If no importance is attached to the infections, naturally no careful search will be made for them, and the physical assaults on the gland will continue.

5. The administration of iodine in small doses over long periods of time, the dose being adjusted to the individual case.

In advocating iodine administration to patients with hyperthyroidism the writer is violating a kind of Galenical dogma that has persisted in medicine for many years. In a recent paper I have pointed out the reasons therefor and have described its application to the different stages of the disease. Not all writers on the subject, however, are opposed to iodine administration to these patients. Marine and Lenhart have found no disturbances to follow its use. In isolated cases others have reported benefit. Most of the discussion about the matter is like that of Kendall based on theoretical consideration only.

The writer believes iodine administration is an essential part of the medical treatment. During the last five years I have given iodine to more than 1,100 patients having toxic goiter and have seen very few instances where it did harm. In most of them immediate improvement resulted, and its effects are so decided that there can be no doubt of the iodine need in these patients. No other substance will take its place. The thyroid gland in hyperthyroidism is poor in iodine. The amount varies within wide limits, but from analyses made by the writer on thirty hyperthyroid glands the following contrasting figures were obtained:

Average of 300 normal glands:
Iodine per gram of fresh gland.....0.364 milligrams
Average of 30 hyperthyroid glands:
Iodine per gram of fresh gland.....0.095 milligrams

The thyroid gland cannot be normal in either structure or function unless it has an adequate supply of iodine. If no iodine is supplied as such, then the iodine of the food supply must be relied upon. In the recent report of Marine and Kimball they state, "Iodine should not be given in any frank case of exophthalmic goiter unless the patient can be daily observed, and then it should be administered only in milligram doses." I believe this caution is based upon theoretical grounds and not upon clinical experience. In 95 per cent. of the patients it is safe and desirable to give one drop of the saturated solution of sodium iodide twice daily in the beginning. In terms of iodine this is equivalent approximately to 75 milligrams of iodine in twenty-four hours. Smaller doses are rarely necessary and they are not therapeutically effective. In fully 50 per cent. of the cases of frank hyperthyroidism it is possible and desirable to increase the dose after two to three weeks.

The patient must be kept under observation, and the amount of iodine salts prescribed varies with the patient's condition, but it is small as compared with the amounts prescribed in other conditions.

These five cardinal principles in the treatment of hyperthyroidism cannot be neglected in any case. Other measures subsidiary to these may at times be useful and necessary with certain patients, but they must be recognized as having a subordinate position and their employment must never lead to a neglect of a full study and treatment of the patient with the five cardinal points in mind. To subject a patient to psychotherapy, and overlook badly infected tonsils and teeth, is not good practice nor is it good sense. To put a patient to bed and administer antithyroid serum, while neglecting to correct focal infections and intestinal toxemia, is equally bad practice. When these five principles are intelligently applied there will be little need for going beyond them. Heterogeneous mixtures of ductless gland and tissue extracts will not often find a useful place in this program. In fact medical treatment of hyperthyroidism is not so much an attempted application of the vague generalities and indefinite hypotheses of popular endocrinology as it is an adherence to fundamental principles in taking care of the sick.

116 East Fifty-third Street.

DIAGNOSIS OF TOXIC THYROID STATES BY A SERUM FIXATION TEST.

A FURTHER REPORT.

By WILLIAM N. BERKELEY, A.B., Ph.B., M.D.,

NEW YORK.

ATTENDING INTERNIST AT THE GOOD SAMARITAN DISPENSARY.

A short notice of the curious and remarkable fact that the serum of patients with toxic thyroidism will under certain circumstances bind complement, and that the test may prove of diagnostic value was published by the writer in the Medical Record[1] last year.

Further work seems to confirm the opinion that the test as a diagnostic resource is distinctly helpful. The technique worked out for me by Mr. John Koopman of the Wassermann Laboratory, New York Department of Health, is as follows:

"The blood of some patients who show symptoms of Basedow's disease binds complement in the presence of an antigen made from normal thyroid glands of dogs or guinea pigs.

"The reaction may be due to a specific thyroid substance which combines with an antibody in the blood of the patient.

"The best method of preparing the antigen which we have been able to find is as follows: The glands are obtained under aseptic precautions as soon as possible after the animals have been killed. Each gland is trimmed carefully, and minced finely with sterile scissors. The whole mass is then ground in a mortar with a measured quantity of washed and sterilized sand and of dry sodium chloride. The amount of sand is of no importance, but the salt should be added in the proportion of 1/10 gram to each gram of gland used; a few drops of 2 per cent. aqueous solution of tricresol are added for each ten grams of thyroid. This mixture is bottled and laid away in the ice box. For use it is made up with distilled water, using 10 c.c. of water to one gram of the original amount of gland. The sand and solid matter are removed with the aid of a centrifuge.

"It is best (but not absolutely essential) to use the mixed glands of five or six dogs (or guinea pigs). As at present prepared, the extract contains much extraneous matter which takes no part in the reaction; if some method of securing the antigenic substance free from all foreign matter could be devised, the specificity would be enhanced. As far as we have gone, we know that the antigen slowly deteriorates, even when kept under the best conditions, and after about three weeks it is necessary to obtain a new supply. Drying instantly spoils its antigenic properties and it does not withstand heating to 50° C. for fifteen minutes.

"The test is set up in the form of a titration, using a constant amount of serum which is not more than one-quarter of the least amount which is anticomplementary. The antigen is used in varied amounts, beginning with an excess and ending with the least amount which can be expected to give fixation. The exact amounts used will depend upon the total volume of the test the worker is accustomed to using. At the same time an antigen control is made with the same quantities of antigen as are put in the test. This procedure will obviate the necessity of putting in a separate titration of the antigen before the test itself is made. The result is indicated by the difference between the quantity of antigen which is anticomplementary of itself, and the quantity which binds complement in the presence of serum. A negative serum with the antigen will often bind less complement than the antigen alone.

"A serum is considered positive when it binds complement in the presence of one-half or less than one-half of the anticomplementary dose of antigen and the smaller the amount of antigen necessary for complete fixation the stronger is the reaction. Fixation is carried out for from four to six hours in the ice box. At the present time the range is short, but with improved methods of preparing the antigen it is hoped the range will become greater.

"Besides tests on human glands and human tumors (*i.e.* thymoid tumors), we have tried the glands of some other animals, namely, guinea pig, bullock, and pig, and we find that only guinea pig glands give results comparable with the dog antigen.

"Much more work remains to be done on fixation results with extracts of true exophthalmic goiters. These are now very hard to get in New York operating rooms, as surgical removal of them has gone out of fashion, and when gotten we have not been able to devise any way of keeping them in fit condition for antigen formation for more than two or three weeks."

The total number of tests, diagnostic and control, amounts now to about 250—upon almost as many subjects. The controls have covered a wide range of ages, diseases, and dyscrasias, except the acute infectious diseases. All the controls were negative except one, which I have previously discussed.[2] The number of thyroid cases is about eighty-five. Of these about twenty-five were chronic or subchronic goiters in which a hypothyroid condition was to be suspected. In only one of these did we get a positive result—due, possibly, to immunological conditions touched on below. Of the re-

maining sixty, fifty reacted positively. In all these the clinical course of the disease seems to have borne out the diagnosis.

The positive tests have run all the way from one-plus to four-plus, and in those cases where we had opportunity to examine the same patient at intervals of six months or a year, the serum test has appeared to keep pace with the clinical course of the disease, the reaction disappearing when the patient had recovered or, as happens now and then, had passed over into a hypothyroid condition. Of the remaining ten cases it is probable that several were true toxic thyroidism, albeit the serum test was negative.

The occasional negative test in a true case is explicable on ordinary immunological principles, though many more cases must be observed before one can be reasonably assured of the correctness of this view.

One case, adult female, in the care of a medical friend in this city, developed the disease with fulminating acuteness. She was suddenly seized with dreadful nervousness, fever, tremor, tachycardia, and exophthalmos, with a small soft thyroid gland. She died in a few days. Her serum was negative.

Another acute case, also a woman, living a few weeks, was negative till a few days before her death, when the serum was two-plus. The explanation here seems to be merely that the patient's system was overwhelmed with toxic material; there was no time for the development of antibody. A similar case in my own practice, seen and tested three weeks after the appearance of active signs of toxic thyroidism, was negative. I have not been able to get another specimen of blood from this patient in order to verify the first test.

The common time allowance for the development of diphtheria antitoxin in horses is from four to six weeks and more; for sheep-cell antibody in rabbits, four weeks; the Widal reaction appears about the third week in typhoid fever, and is sometimes delayed till convalescence. We may reasonably anticipate some similar delay in the case of thyroid toxins in the human body.

On general immunological principles we may also expect that some patients under unfavorable physical conditions will make no antibody at all for a long time, and that again some patients will make such an excess of antibody that it will persist as such in the patient's serum, like the four-plus Wasserman in syphilis, long after clinical signs have disappeared.

This consideration probably offers an explanation of the four-plus reaction in the chronic goiter case mentioned above. This was a school girl of sixteen years from Michigan. She had had an enlarged thyroid since her thirteenth year (probably endemic goiter) with a history of mild nervousness. But at the time she was sent to me (through the courtesy of Dr. J. Perry Seward of this city) she had no such symptoms. Her temperature was 98°; pulse standing, 84; there was no tremor, and her eyes were normally situated in the orbits. Her condition was in some regards more suggestively hypothyroid, and she did well on small doses of thyroid gland, and two grains twice a day of potassium iodide. Six weeks later her thyroid had diminished in size, but the serum reaction was still four-plus.

Evidently, therefore, the serum test, if it is to be really useful in diagnosis, must be considered as a part of the diagnostic symptom complex. It is not necessarily more pathognomonic than *B. diphtheriæ* in the pharynx of a healthy "carrier" is of diphtheria.

The test has been of special value in tobacco (cigarette) poisoning, in cases of thyroid tachycardia without either popped eyes or struma, in menstrual and post-puberty enlargements of the thyroid, and in "spent" cases of exophthalmic goiter. Here the patient often has a permanently damaged and irritable heart, a cystic and nodulated gland, eyes still protruding, and even a tremor, so that a diagnosis of hypothyroidism from clinical symptoms alone is almost impossible.

As a laboratory procedure the serum test must be compared, of course, with other laboratory tests, of which the adrenalin test of E. Goetsch[2] and the basal metabolism test are those at present most in favor.

In respect of the Goetsch test, the evidence is contradictory. L. F. Barker[3] thinks it valuable as a confirmatory sign. Of three medical associates here in New York with some experience of it, two (personal communication) believe it very unreliable, and one even thinks it dangerous. C. H. Mayo[4] declares it "altogether too variable" to justify dependence. A recent report by M. S. Woodberry[5] at the Clifton Springs Sanitarium, in which the test was tried, concludes that an adrenalin injection reacting positively indicates a generally increased excitability of the sympathetic nervous system which may or may not be of thyroid origin. Irene Sandiford[6] injected thirty-nine patients suffering with various disorders of the ductless glands forty-six times with 0.5 c.c. of 1: 1000 adrenalin. There was an invariable increase in the metabolic rate, but no relation was found between the intensity of the adrenalin reaction and the degree of hyperthyroidism or hypothyroidism. Marine and Lenhart[7] tried similar tests on groups of normal and of thyroidectomized rabbits, with similar results.

As to the Marine and Lenhart experiments, it should in fairness to Dr. Goetsch be noted that owing to the number of accessory thyroids in rabbits excision of the large glands may not always materially modify the thyroid metabolism. I do not think, therefore, that the summary dismissal of the adrenalin test on the above grounds in a recent editorial of the *Journal of the A. M. A.*[8] is as yet justifiable. The test requires a much more extensive try-out.

As regards basal metabolism, even an abbreviated bibliography of this wonderful and rapidly growing subject would far exceed the limits of this paper. Metabolic studies have come to stay, and they are doubtless destined to play an important part in the future of therapeutics, and specially in the future of thyroid diseases. Briefly, a large number of determinations with standard apparatus seem to prove that hyperthyroidism is associated with a percentage rise in the basal metabolism of 30 to 100 per cent. Plus and minus variations of 10 to 15 per cent. occur in health. Larger plus variations occur in severe anemias, in leukemias, and in fevers. Cretinism and myxedema show a metabolism of minus 15 to minus 40 per cent.

For the time being the main objections to tests of basal metabolism as a clinical resource are the serious inconvenience and expense of such determinations. It is alleged[12] that the cheaper apparatus is unreliable, and only the standard "open-circuit" machines, costing from $1500 to $3000, should be used. These are not portable, and consequently the test would be limited to a few of the wealthier hospitals in the larger cities, and entirely inaccessible to the general medical public.

All these statements are probably exaggerated, and in any event it is likely that by technical improvements in the next few years they will largely be done away with. More essential objections are fairly summarized by W. S. McCann,[9] who describes the present stage of metabolism work as follows: "Lesions of the thyroid are not the only ones which lead to marked quantitative changes in the metabolism. In the anemias, in leukemias, and in certain of the rare diseases, not to mention the fevers, the metabolism may be greatly increased without any marked thyroid disorder. Diagnosis must depend on other things than a metabolism test. A report of high or low basal metabolism has just the same kind of significance as a high or low leucocyte count. Both may be admitted as contributory evidence." There are already a number of cases[10, 11] reported—possibly very exceptional ones—where the diagnosis of hypo- or hyperthroidism seemed clinically necessary despite the fact that the basal metabolism was not materially altered.

In conclusion, it will be enough to say of the serum test that while experience of it is so far limited, it promises well. It costs no more than a Wassermann, it is easily and quickly done in any serum laboratory, and if the present ratio of positive reactions is maintained, it should, along with other signs, prove to be of distinct value in the diagnosis of one of the most troublesome diseases the internist has to deal with.

What I most hope for it is that, in conjunction with the basal metabolism test, it will finally settle the long discussed and troublesome question whether there does or does not sometimes appear as a clinical entity a true toxic thyroidism in the strict sense of the word; by this I mean a thyroid dyscrasia developing without quantitative change in the normal thyroid output.

THE NEED OF CALCIUM-THERAPY IN TUBERCULOSIS.*

BY F. TWEDDELL, M.D.,
GREAT NECK, N. Y.

ONE day in 1918 I came across Fishberg's[1] quotation that Fisac of Spain reported in 1909 that "all workers in lime and plaster of Paris were immune to tuberculosis despite the fact that they live in squalid dwellings and are underfed." Believing that the first step towards discovering the remedy for any particular disease is to find an industry or occupation in which this disease does not exist, Fisac's statement, if true, meant to me that some compound or preparation of calcium would cure incipient pulmonary tuberculosis if used in the most effective manner.

In order to confirm Fisac's findings, I obtained from the U. S. Geological Survey Department a list of manufacturers of lime and plaster of Paris in the northeastern states and asked the managers how many cases of pulmonary tuberculosis they had had among their men. In their replies they stated that no cases of pulmonary tuberculosis were ever noticed among their employes, and further some mentioned the fact that their men were unusually free from coughs and colds, and others volunteered the information that some new men when first taken on had coughs and colds and soon recovered from them. Many of these reports were from physicians employed by these firms.

I received similar reports from the largest plants in Canada, from Manitoba to Nova Scotia; no cases of tuberculosis were ever seen. One of these plants had been running over twenty-five years and another over forty years.

It is highly probable that some of these men who were noticed to have coughs and colds on first being employed, were really in the incipient stage of pulmonary tuberculosis, and they recovered. It is unlikely among such a large number of men taken on to work that a few would not be afflicted with this disease, especially as statistics show that about one per cent. of the population have it.

Wishing to know why the dust of lime or gypsum caused immunity to tuberculosis, I asked a chemist to analyze the air in these factories under working conditions, for I suspected the presence of sulphur dioxide or chlorine or other gas. This chemist was very much interested, as he was a sufferer from phthisis. I quote from his report as follows:

"At neither the lime nor the gypsum plants was there a trace of sulphur dioxide or chlorine to be found. I used a very large amount of air, in fact, sufficient so that one part in ten million parts of air would have been detected. I tried to ascertain if there could be any other antiseptic gases present, but I could not think of any. I imagine that the immunity which you have found to exist in lime and gypsum plants can probably be ascribed to the very finely divided particles of calcium oxide and calcium sulphate found floating in the air."

This immunity is therefore due to the action of finely divided particles of lime and gypsum inhaled

*Read before the Sullivan County Medical Society at Liberty, N. Y., October 12, 1921.

into the lungs. Lime in contact with water or the moist tissues of the lungs forms calcium hydroxide, which acts as a caustic and antiseptic and is then absorbed. Gypsum is also absorbed. This action appears to be specific in early pulmonary tuberculosis, for some unknown reason, the same as quinine is specific for malaria.

Renon[2] reported in 1906 that in a limestone region in the village of Yonne, where there had been lime-burning furnaces for ten years, among 200 employes, almost all alcoholics, none had tuberculosis. The lime kilns even brought about a dimunition of tuberculosis among residents in the neighborhood.

De Langen[3] reports that pulmonary tuberculosis is not encountered in children in the Dutch East Indies. He states that many native remedies are used, many of which contain lime. It seems, therefore, that calcium acts as an efficient preventive of tuberculosis.

That calcium has healing properties in tuberculosis there can be no doubt. Several observers have noted this. Osborne[4] states that "tuberculous lesions are cured by local deposits of calcium salts. . . . Only about 0.01 per cent. of the calcium of the body is in the soft tissues; it is practically all in the bones. . . . Tuberculous patients need an excess of calcium."

Beasley[6] points out that tuberculous processes in the lungs are quieted by calcium salts, and that autopsies reveal calcium deposits on previously unknown tuberculous lesions. Patients succumbing to tuberculosis show scantiness of these deposits in direct ratio to the rapid progress that the disease has made. He remarks, too, that nature does not attempt to heal other pathological processes in the lungs with calcium salts. This last sentence appears to indicate that calcium is *the* specific for tuberculosis and taking into account the immunity to tuberculosis of workers in lime plants, there is no other conclusion possible.

The fact that healing is effected by calcium is noted by Behan,[6] who states that where there is inflammation of the bone, there is a great deposit of calcium salts in the inflamed area.

The value of calcium is greatest as a preventive of tuberculosis. As mentioned above, men who are underfed and badly housed or alcoholics, do not acquire tuberculosis, provided they work in lime kilns where they inhale sufficient dust of lime which is absorbed. While coal miners almost invariably suffer from asthma, anthracosis, etc., I can find no mention of these conditions among workers in lime and gypsum. These calcium compounds not only do not cause irritation, but are absorbed, which is not the case with coal dust.

The following extract from a chemist's letter appears to confirm my statement that calcium in the food acts as a preventive of tuberculosis. He states that his parents came over to this country from Iceland about fifty years ago. "At that time pulmonary tuberculosis was practically unknown there, in spite of the fact that sanitary conditions were extremely bad and the people very poor. Since then the island has become extremely prosperous and the housing conditions have been immeasurably improved. Yet the people at the present time are dying like flies from tuberculosis. Change of diet is responsible for this condition. Previously it consisted mostly of whole wheat or rye bread, oatmeal, milk, and fish. At the present time the milk is mostly converted into butter and cheese, while the whey, which contains most of the mineral salts, is thrown away. The bread is made entirely of white flour, and instead of drinking milk, they take coffee and tea."

To obtain more information on this subject I wrote to the professor of medicine in Iceland and made inquiries about these statements. He replied that "In the decade 1861-70, tuberculosis was practically unknown. We were not totally free from it, but among some 5000 patients, J. Finsen found only four with tuberculosis pulmonum. In 1911-15, of 1259 deaths there were only 101 from tuberculosis pulmonum. There is no doubt that tuberculosis is far more prevalent now than it was fifty years ago. The food is now richer than before, and the bread is made from rye. The fishing population takes much coffee and is in want of milk, but some of the worst hotbeds of tuberculosis are just the farms, where milk is abundant and food on the whole very liberal. Deficiency of calcium is very unlikely."

This statement seems a contradiction, but the above chemist and Halldorson, whom I quote below, show that the milk, although plentiful, is not consumed as a beverage. Halldorson,[7] a native of Iceland, confirmed the chemist's investigations by stating that in Iceland the people have lived for centuries on some sour milk products, making a kind of junket. As soon as the people gave up eating this sour milk, tuberculosis became a scourge.

In regard to the calcium content of our food, investigators have pointed out that there is an insufficiency of calcium as well as of other minerals, all of which are essential for perfect health. Demineralization of our daily food does not seem to have attracted the attention that it deserves. Sherman[8] has stated that the ordinary mixed diet of Americans and Europeans, at least among dwellers in cities, is probably more deficient in calcium than in any other chemical element.

McCann[9] characterizes our food as "processed, bleached, colored, denatured, degerminated, demineralized, and chemically treated." Foremost among these denatured foods are bread, milk, cereals, and sugar. Whole wheat bread is difficult to obtain, or is not usually eaten, only white bread. The outer part of the grain of wheat has to be removed to obtain white flour, which is practically all starch. The husk contains most of the mineral matter, including calcium, which is discarded.

Nearly one-fifth of the mineral contents of raw sugar is calcium. In the manufacture of white sugar all of the mineral matter is removed. Molasses and refiners' syrup are by-products of sugar and contain practically all of the mineral matter. White sugar will not crystallize unless the mineral matter is removed. It is the calcium which prevents crystallization.

Candies are made from white sugar or glucose, neither of which contain mineral matter. Sugar and candy are therefore demineralized carbohydrates. Statistics show that about eighty-five pounds of sugar per capita are consumed every year in this country. The mineral loss in our daily food from this source alone must be enormous.

The mineral matter contained in milk is also

tampered with owing to improper or inadequate arrangements for transporting or handling milk. Raw milk contains calcium and other mineral matter in natural organic combinations. Pasteurization partially, and sterilization almost wholly destroy this natural state, changing it into salts which cannot be absorbed so readily. Calcium is most readily assimilated from raw milk, raw eggs, raw sugar, fresh vegetables, and fruits.

Milk contains a larger percentage of organic calcium than any other food. Halverson[10] states that one pint of milk contains 0.5 gm. calcium, which is sufficient to maintain the daily calcium equilibrium in an average man. This statement is true in regard to the average healthy man, but we all know that no amount of milk or other food or even drug has any marked influence on the course of tuberculosis, as at present administered. Its value is prophylactic, not curative.

Some observers affirm that deficiency of fresh vegetables increases malnutrition and tuberculosis, as for instance, Selter and Nehring,[11] who reported that as soon as fresh vegetables come into the market, the mortality of tuberculosis drops and it is lowest in the fall. The poorer quality of the food toward the close of winter accounts for the higher mortality in the early summer.

Grenfell,[12] speaking of the inhabitants of Labrador, states: "Consumption is the main enemy of these people, who live here in one of the purest atmospheres in the world . . . and from that in one form or another most of the people die. . . . One out of every three or four deaths on the coast is due to tuberculosis." I am unable to say whether this excessive mortality is due to the absence of acquired immunity or to the deficiency of calcium in the food. Probably both factors are responsible for this deplorable condition.

Not only calcium in the food, but calcium in the soil appears to be a preventive of tuberculosis. Whitney[13] reports that indigenous phthisis is practically unknown in Colorado, but he gives no reasons for this immunity to tuberculosis. However, North[14] reported in 1914 that the calcium content of the soil had a remarkable influence on the incidence of tuberculosis, that humid soils have an average of only 0.108 per cent. calcium oxide, whereas the average of arid soils is 1.362, or more than twelve times as much. Arid States like New Mexico, Colorado, Arizona, and others have an average of over 2.37 per cent. calcium oxide. New Mexico heads the list with nearly 5 per cent. Tuberculosis among the native white population is rare in these States. The dry air laden with dust containing lime is inhaled and the vegetables and fruits contain more lime. It is not as perfect an immunity as is enjoyed by workers in lime kilns, who are *all* immune.

In the treatment of tuberculosis, calcium is needed not only for its healing properties, but also for its alkaline action to overcome the hypoalkalinity or acidosis, which is almost always present. Many authors are agreed that there is a decided acidosis in certain stages of tuberculosis. This is due to the toxemia, the fever and the depletion of alkaline salts. In Pritchard's[15] opinion, all chronic conditions of malnutrition of whatever kind or from whatsoever cause, finally terminate in an acidosis. Forchheimer[16] also states: "There is reason to believe that the backsets to which many tuberculous invalids are prone without apparent cause often find their explanation in a recurring acidosis."

During the past few years I have been using a preparation of calcium for the dressing of cuts and wounds in my office, and I was struck with its remarkable healing properties. In connection with what I have already told you, it came to my mind that wounds could not heal without the presence of calcium. I thought, therefore, that if I could find a place on this globe where there was no calcium in the air or water or food, I was sure wounds would not heal at all, or very slowly. Such an unfortunate locality is Aden at the southern extremity of the Red Sea. Consequently I wrote to the Principal Medical Officer there and asked him if it were true that wounds and fractures do not heal at Aden, owing to the deficiency of calcium. In his reply he stated that: "In Aden, ulcers, edema of ankles, boils, and receding gums are of very common occurrence; further, wounds and ulcers and such like are invariably slow in healing. These symptoms are generally attributed here to the scanty supply of fresh vegetables and fruit. All the drinking water in Aden is condensed, and I am of the opinion that the absence of lime salts, protozoa, etc., is to a great extent accountable for these symptoms, as they are also particularly common on the Red Sea islands and in the lighthouses in the neighborhood."

About the time these letters were written I met the former American consul at Aden and his wife who had both spent a couple of years there. They assured me that wounds and fractures were so slow in healing that the white population so affected left Aden for India or for home.

It appears certain that calcium as heretofore administered has had no decided curative value in the treatment of tuberculosis. The oral administration of calcium salts, or the taking of foods rich in calcium, such as milk, eggs, etc., does not appear to have appreciably improved the patient's condition. Whether this failure is due to the abnormal loss of calcium in this disease or to insufficient absorption of calcium by the tissues, it is difficult to say. Many calcium salts, such as calcium chloride, calcium iodide, etc., have been given intravenously, but they do not appear to be specific; on the contrary they are dangerous, often producing depression and even collapse and irregularity of the heart. The salts of calcium cannot be utilized by the tissues, whether given by mouth or intravenously, as the body does not tolerate a crystallizable substance any longer than it takes to change it or excrete it, for a membrane is permeable to ionizable salts and therefore the salts are excreted as rapidly as possible. Max Kahn[17] gives an excellent résumé on this subject.

Judging from the anatomy and physiology of the lungs there are *only two direct* and efficient ways of treating tuberculosis of these organs. One route is by means of inhalations and the other by intravenous injections. There is *no other road by which to carry medication direct to the remotest parts of the lungs*. By the first method I have used sulphur dioxide only and reported some of my cases[18]. My investigations have shown that practically all men

working around this gas are immune to tuberculosis, and that no ill effects have so far been noted. I do not advocate its use now except in incipient cases. I have had no facilities for employing inhalations of the dust of lime or gypsum in the treatment of phthisis, although it seemed to me that it would be more efficient and ultimately more productive of good than sulphur dioxide on account of the absorption of calcium. It is surprising that since Fisac's[1] report no efforts have been made to treat patients by allowing them access to a lime factory under working conditions. Max Kahn[11] quotes a recovery from phthisis by the accidental inhalations of the dust of lime, thus there can be no danger in giving this a trial.

In regard to the food, I advise patients to take the ordinary mixed diet, and plenty of vegetables and fruits, milk, and eggs, all fresh and uncooked, and if possible the shells of fresh raw eggs ground to powder. These shells contain a greater percentage of organic calcium than any other substance. The shells of boiled or stale eggs will not do, as boiling or long exposure to the air turns the organic calcium into calcium carbonate ($CaCO_3$) or marble, which is not absorbed.

For over three years I have been using intravenously a preparation of calcium, said to be in colloidal form, made for me by a chemist in New York, which I have found to be most useful. Each dose of 10 c.c. contains: calcium, 0.048; iron, 0.0024; guaiacol, 0.015; sodium salicylate, 0.065; mercurous iodide, 0.0006; iodine, 0.0003; sodium chloride, 0.240. The preparation has been extraordinarily efficient in the treatment of incipient tuberculosis, but I have also used it for all cases showing acidosis or deficiency of calcium. I will report a few cases to show you its action.

Case I.—R. L. of Great Neck, 23 years, mechanic, came to my office March 17, 1919. Chief complaint anorexia, loss of weight and strength, and dyspnea on exertion. Has had a cough since September, 1918, and sputum has occasionally been blood streaked. Physical signs negative, except for occasional râle at right apex after coughing. Pulse 96. Given intravenous injection. March 23, 1919, felt better and stronger. Pulse 84. Second intravenous injection and instructed how to use sulphur dioxide inhalations. Sputum was not examined, as patient failed to bring it to me. A few days later he went to stay with some relatives in Massachusetts, where he decided to take a rest, but drove a team of horses daily. A month later he returned and went back to work. He kept up the sulphur dioxide inhalations until middle of July, when he told me he had no more cough, no dyspnea, and felt perfectly well. been well ever since. He had a total of nine intravenous injections. He has been perfectly well ever since.

Case II.—W. T. G. of Great Neck, a painter, 35 years, married, and six children, was sent to me for treatment by Dr. D. C. Byrne of Great Neck. This patient had influenza in October, 1918, which left him very weak. He has had a cough since May, 1919. Came to my office April 13, 1920; had lost flesh and strength, had dyspnea on exertion, and lately had night sweats. The sputum was positive. Had not worked for past ten days, as he was too feeble. Examination showed crepitant râles at both apices, weight 145¼ lbs., pulse 100 at 7 P. M. Was given intravenous injection of calcium and instructed in the use of a tank of sulphur dioxide. April 17 the patient states he went back to work the very next morning after the first intravenous injection, as he felt so fine. Pulse 80 at 7 P. M. April 21, pulse 82, and the patient has gained 3½ lbs. in a week. June 18, pulse 76 at 7 P M , weight 153¾ lbs., has not coughed for a whole week, and is perfectly well. Sputum examined at this time and found negative. No physical signs in chest. He has been well ever since. He had a total of nine intravenous injections.

It was just a matter of luck that these two patients got well. They went back to work far too soon, the mechanic a week after beginning treatment, and the painter the very next day. The latter was working twelve hours a day after a week's treatment, but I was able to stop the overtime work, and reduce it to eight hours. I was not so fortunate in some of the other cases; here are two instances:

Case III.—A. E. of Great Neck, a laborer and farmer, married, three children. Came to my office February 3, 1920. He had influenza in February, 1919, which left him very weak; later he developed a cough, lost weight, strength, and appetite, and had dyspnea on exertion. Has not been able to work for two months. Sputum was positive. Examination showed crepitant râles at both apices in front in the upper three interspaces and down to the spines of the scapulæ behind. Pulse 100. February 4 and 9, intravenous injections of calcium. February 12, instructed in the use of the sulphur dioxide tank. March 1 was feeling so well that he worked from daylight to 8 A. M. on his farm, then drove a team of horses for a contractor until 4.30 P. M., and worked again on his farm until sunset. I protested, but without avail. March 22, pulse 72 at 7 P. M.; gave third injection. April 12, pulse 64 at 7 P. M. May 31, pulse 70 at 7 P. M.; gave fourth intravenous. July 4, pulse 68, no physical signs in chest. On March 29 weight 152½ lbs.; May 31, 144¼; July 4, 146½. Henceforth he gave up all treatment. I beseeched him to come to my office, but he refused. The loss in weight shows that he was overworking. I saw him at work still early this spring, but about June 21 he had several hemorrhages and passed away rapidly.

Case IV.—J. B. of Great Neck, 21 years, bloody sputum occasionally since May, 1918; sputum positive, râles at both apices. Hemorrhages on January 28, 1919, a teaspoonful of blood every time he coughed. Temperature 102°, pulse 120 at 4 P. M.; given first injection. Hemorrhage stopped after three hours. Wanted to get up next day. Three days later, February 1, 1919, at 5 P. M., temperature 99°, pulse 100; second injection given. February 3, at 4.30 P. M., temperature 97.5°, pulse 72. February 4, insisted on getting up, as he felt so well. As soon as he was up he went around to see friends and received many visitors. His temperature never went above normal during the next month, but his pulse was always high, in the nineties. He refused to take my advice and rest in bed or on a couch. On March 4, 1919, I gave him the fifth injection, and a few days later he went to a farm up-State to take his own cure, and died about a year later.

Case V.—A. H. of Bayside, 21 years, single, came to my office May 6, 1921. Had rickets up to three years of age, scarlet fever at five years, which affected her heart and left it with a leaky valve. Cannot play or run or go upstairs without dyspnea. A year ago she weighed 145 lbs., two months ago 126 lbs., now 103½ lbs. She has been ill in bed for the past six weeks with shortness of breath, loss of appetite, loss of strength, and feels very tired all the time; does not sleep well, coughs occasionally. Examination: Pulse 96 and regular, a loud systolic murmur over precordium, loudest at apex, few crepitant râles at both apices and occasional râles scattered throughout lungs, thickened pleura on lower left side in axillary line, winged scapulæ, depression above and below the clavicles. Strong mouselike odor of skin. Sputum not examined, as she neglected to forward it. May 7, first injection, pulse 92 and intermittent, instructed in use of tank of sulphur dioxide. May 10, pulse 68, regular, eats well, sleeps well, and wants to get up; gave second injection. May 13, has only slight cough on getting up. July 4, has been at work in a factory since a week, weight 118¼ lbs., feels well, pulse 104, occasional râle at right apex only; gave third intravenous. August 8, 1921, feels well, pulse 94, weight 125 lbs., lungs clear, still works in factory; did not want injection, as it made her eat so much, but I gave

the fourth injection. October 10, not doing so well, works in factory, often goes to parties and dances at night until 3 A. M.; has begun to cough again. Pulse 104, many râles at both apices, has had no treatment for two months, weight 123½ lbs.

Here is a typical case of a patient going back to work too soon, neglecting treatment and suffering a relapse. The following two cases show the use of these injections for other than pulmonary cases:

CASE VI.—Mrs. Z., 39 years, has had tuberculosis for six years, has cavity at left apex. Uncontrollable diarrhea for five months. After the second injection she had no diarrhea for the next five days that she stayed under my care. She returned to her home, which was in another State.

CASE VII.—Mrs. M. A. P., widow, 24 years, aphonia for seventeen months, night sweats occasionally, fever afternoons, not much cough, few râles at right apex, sputum positive. February 12, 1919, first injection, and given instructions in use of tank of sulphur dioxide. Returned February 17 with sister, and both told me that five hours after the injection the patient used her voice better and spoke some words aloud. This condition lasted until the early forenoon of the next day. Had altogether three injections, and each time this curious phenomenon occurred. She took the sulphur dioxide inhalations faithfully and went back to work six weeks later. I quote from her letter of August 4, 1919: "I felt greatly benefited by the injections; my voice seemed to be more distinct after each injection. My voice has not come back entirely, but I am able to speak much louder now than I did before the injections. I seemed to notice a change almost the same night. Members of my family and my friends noticed the change, too, as before I could only whisper. I have not been able to use my voice for seventeen months. I go to business every day, have not missed a day since I started in April. I am on my feet all day long and am feeling better than I have in two years. A few months ago I was not able to work."

In conclusion I wish to say that I have tried this preparation of calcium in all stages of tuberculosis, but recommend it only for incipient cases where its action is prompt. In the more advanced stages the patients feel better after an injection, but I doubt whether it does them any permanent good. I have always used it in conjunction with sulphur dioxide inhalations except in cases with hemorrhages, where I use it alone. It is a curious fact that this preparation contains iron in an alkaline solution, only about ⅛ of a grain to 10 c.c. I have this information from the analysis by another chemist. Now iron is incompatible in an alkaline solution, for it is always precipitated. Iron can be present in an alkaline solution only in colloidal form. Therefore, this preparation appears to be a colloidal compound, but this statement awaits verification. All salts are rapidly excreted by the kidneys and intestines, whereas colloids are absorbed. This accounts for the extraordinary efficiency of this preparation, for it contains only about ¾ grain calcium to the dose of 10 c.c. The matter now rests in your hands and as Leven[19] says, "Well studied, well experimented, the medicine that has cured once should always cure."

RATING LOSSES OF INDUSTRIAL VISION UNDER THE NEW YORK STATE COMPENSATION LAW.*

BY WILLIAM MEHL, M.D.,

BUFFALO, N. Y.

THE New York State Compensation Law has been in operation for seven years. Many thousands of industrial accident cases have been adjudged under this law. The Appellate Courts have reviewed hundreds of contested decisions and awards and have made certain rulings which must govern the interpretation of various provisions of the law. Amendments have been enacted from time to time, ostensibly for the purpose of removing difficulties encountered in making awards; but—and I consider this point most significant—the principle which governs permanent disabilities has remained unchanged, and is essentially the same to-day as it was in 1914.

The principle which governs permanent disabilities caused by accidental injuries, bears no *direct* relation to the damage done to the earning ability of the injured person in his particular vocation. A watchmaker is paid compensation for exactly the same number of weeks as an unskilled laborer, when both have suffered an equal reduction of vision. A violinist and a maker of fine instruments are paid for no longer period than a truck driver, for the loss of an index finger. A man in a sedentary occupation gets pay for the same number of weeks, for the loss of use of a leg, as the man who has to climb telegraph posts or walk on elevated steel girders. The compensation is fixed for the limb and the organ which has been damaged permanently, regardless of the resulting occupational handicap the injured person has sustained. In other words, there is no strict application of the economic principle as regards permanent physical impairments.

At the first glance, the schedules for permanent impairments appear altogether arbitrary. They did look so to me, I must confess, till I inquired into the matter further. I learned that while no exact justice was assured to each individual, there was an attempt made to provide for what is called *average* industrial justice. The occupations covered

*Paper read before the annual meeting of the New York State Society of Industrial Medicine, at Syracuse, N. Y., December 7, 1921.

by the law in this State include many in which a high degree of skill and corresponding physical efficiency are required, as well as those which make comparatively small demands upon either skill or physical soundness. The schedules incorporated in the law for the compensation of permanent impairments were calculated to represent the losses of earnings experienced by the industrial workers, taking a general average, so far as the State of New York is concerned. In a State where skilled labor predominates to a larger extent than in New York the schedules would have to be correspondingly more generous, if the same principle were applied; and, on the other hand, in a State where the proportion of unskilled labor is greater, the schedules would be correspondingly less generous.

This principle of *average* industrial justice I should like to call, for greater convenience in my present paper, a *general industrial* principle, by way of distinguishing it from the more *specifically economic* principle which governs the compensation laws in most European countries and to some extent also in Canada and the State of California.

There are, in fact, three principles by which permanent losses may be rated:

There is, first, the purely *physical* principle by which the medical examiner determines the degree of damage done, regardless of general or specific economic depreciations.

Second, there is the *specifically economic* principle by which an injury is estimated according to reduction of earning ability, which the individual has suffered in consequence thereof in the pursuit of his chosen vocation.

Third, there is the intermediary *general industrial* principle which fixes the monetary value of normally functioning members and organs of the body as a general industrial asset and rates the sustained physical impairment according to established schedules.

As I shall deal in my present paper more particularly with the rating of permanent reductions of eyesight, and as the law in the State of New York takes no account in this matter of the actual economic losses the injured individual must face in consequence of the physical damage, we shall be concerned here only with the first and third principles. In other words, we have to do here, on the one hand, with the determination of the actual physical impairment, which must be established by the medical examiner, and, on the other hand, with the legal rating of such physical impairment, which is primarily the responsibility of the referees of the State Industrial Board.

Unless we keep in mind these few simple practical facts, when we discuss particular phases of the law and their proper interpretations, we are sure to become entangled in irritating, wasteful and fruitless controversies.

Medical men cannot be expected to be conversant with the Compensation Law, the various changes it has undergone, the court decisions regarding it, nor even the principles upon which it is established. Our particular care is to examine and diagnose accidental injuries and whatever consequences may have resulted from these, and then to report our findings and opinions to the officers charged by the State with the making of awards under the Compensation Law. If we could be permitted to adhere strictly to these lines, and take no account of the legal aspects of the determination of compensation cases, we should be able to confine ourselves to giving straightforward statements of purely scientific findings and then leave the legal interpretation of these findings to the officer or officers whose business is to administer the law.

The rough-and-ready way in which compensation cases are handled in practice has wiped out, to some extent, the lines of division of responsibility which I have suggested. Experience shows that, as a matter of fact, the medical examiner is called upon quite frequently to give not only his scientific findings but to interpret them for the State in accordance with the existing law. That the law has fixed certain principles for such interpretation, which a medical man cannot reasonably be expected to know, does not appear to have had proper consideration hitherto.

It is not my intention to have the line drawn too sharply. Reasonableness is all I plead for.

The question of what percentage of sight an eye has lost as a result, direct or indirect, of an accidental injury is a case in point. All that the oculist, as such, ought to be expected to do is to determine technically the degree of purely physical impairment sustained, using the peculiar means at his command, and then report. Special training, professional practice and keeping step with new discoveries and developments in his particular field, should attach to his findings a corresponding degree of authoritativeness.

On the other hand, if the oculist is required to go beyond the boundaries of his special field of ophthalmology and even outside of medicine, by being asked by a referee or the State Industrial Board, an employer or insurance carrier, to interpret his findings in accordance with the Compensation Law of the State of New York, it must be evident that he should know the legal provisions relating to the loss of use of an eye, as well as the decisions of the Appellate Courts which define how injuries of the eye shall be rated.

The surgeon who reports on the impairment of a finger by amputation is not required to interpret his medical findings in accordance with the Compensation Law. He tells what phalanx or phalanges have been cut off wholly or in part, and the referee decides on the basis of the surgeon's report what percentage of loss the amputation represents. A similar procedure ought to be possible as regards the determining of the percentage of vision lost by an injured eye. It *is* possible.

Let us take first the determination of the purely physical loss of vision experienced by a previously normal eye as result of an accidental injury. In the vast preponderance of cases this loss can be established by the ordinary Snellen tests which supply the most reliable and universally accepted scientific means for this purpose.

To be sure, the Snellen test applies only to central vision or central visual acuity. The fact remains, nevertheless, uncontested that visual acuity is *the practical working vision*. It is the vision most frequently destroyed or reduced by industrial accidents.

The presence of perfect binocular vision need not

be taken into account at all, as the law in the State of New York makes the impairment of it equivalent to the loss of use of one eye.

As regards the field of vision, or peripheral vision, we all know that an accurate estimate of its partial impairment is next to impossible, as a practical proposition. No two oculists would ever agree in their ratings. And mere assumptions are unscientific. As a matter of fact, traumatic impairments of peripheral vision by itself are so rare that it seems unjust to reduce the allowance for the ordinary eye injuries by suggesting that only one kind of sight has been affected. When there is an extremely rare case of destroyed peripheral vision, *then* is the time to take up this matter for special consideration.

The compensation for eye injuries is small at best, especially if we consider that the loss of vision is compensated not by its actual amount, but after the best correction by lenses which the eye will tolerate. As we are assured that the law aims at average industrial justice, we must draw the only reasonable conclusion that payment on the basis of visual acuity was assumed. This conclusion is confirmed, moreover, by decisions of the Appellate Courts.

Prior to July, 1917, the law made no provision for compensation for the permanent partial loss of the use of an eye. Since July, 1917, compensation for permanent partial impairments are provided for.

Furthermore, the percentage of loss of vision which should be considered equivalent to the loss of an eye was not fixed by the Legislature until 1920, and the new provision did not go into effect till May 5 of that year.

It is well to bear these facts in mind in order that we may obtain a clearer understanding of the decisions rendered by the Appellate Courts in a number of contested compensation cases relating to total and partial losses of vision.

For example, on March 13, 1917, the Court of Appeals ruled that 80 per cent. loss of vision in an eye cannot be considered loss of use of that eye. I refer to the case of Boscarino *vs.* Carfagno & Dragonette, Court of Appeals, 220 N. Y., 323. The Court ruled in this case: "If the claimant still has vision in the eye which equals 20 per cent. of normal, he is very far from having lost the use of the eye."

The Commission, after careful inquiry, decided that 80 per cent. loss of vision *ought to* be considered loss of use of an eye, and placed its contention before the Legislature of 1920. After public hearings on the question, the Legislature added to the provision relating to loss of use of an eye, the following, which is in force at the present time:

"The loss of 80 per centum of the vision of the eye shall be considered to be the equivalent of the loss of the use of the eye, and the loss of binocular vision shall be considered to be equivalent to the loss of use of one eye."

The question now arises, what is meant by a "loss of 80 per centum of the vision of the eye?" Here again, unless we want to indulge in more or less fruitless speculation, we do best to consult first the ruling of the Court of Appeals, which deals with the law as it stands.

Reverting to the case of Boscarino *vs.* Carfagno & Dragonette, we note that the Commission which found the claimant to have sustained a loss of 80 per cent. of vision had based its finding on the report of an examination made by Dr. Weeks of New York City, one of the foremost ophthalmologists of the United States. Dr. Weeks reported as follows: "Vision of right eye 20/100ths, not materially improved with glasses. . . . Field of vision normal in extent." Dr. Weeks, as ophthalmologist, finds further that the reduction of central visual acuity, to 20/100ths of normal represents a loss of 80 per cent. of vision, and his finding is endorsed by the Industrial Commission and sustained by the Court of Appeals. What more can we ask than this? It will be noticed that the reduction of working vision to 20/100ths is called 80 per cent. loss of vision, despite the finding that "the field of vision is normal in extent."

There does not appear to be a single case among the many eye cases passed upon by the Appellate Courts, in which any deduction is made for remaining field vision. Central visual acuity, or working vision, is uniformly called vision. Hence the answer to the question, "What is meant by 80 per cent. loss of use of an eye? is —20/100ths. Incidentally, this indicates that the Snellen test has been accepted as the means for measuring vision.

Taking into account the court decisions, the Compensation Law declares in effect that industrial vision lies between 20/20ths and 20/100ths of normal, 20/20ths representing the minimum of normal working vision and 20/100ths the loss of use of an eye.

Now comes the mooted question how to rate permanent *partial* losses of vision occurring between 20/20ths and 20/100ths. If we adhere closely to the lines laid down by ophthalmology we shall have no difficulty. All we should have to do would be to continue to rate 20/40ths of normal as implying a loss of 50 per cent. of working vision, 20/80ths as a loss of 75 per cent., 20/100ths as a loss of 80 per cent., etc., and let those who administer the law do as they please with our ratings.

In the absence of a legal provision declaring how the permanent partial impairments of sight shall be rated, there is ample justification for adhering to the practice which obtained before 20/100ths was made to stand for industrial blindness.

Scientifically speaking 20/40ths means that central visual acuity, or working vision, has been reduced to one-half of normal. One-half means 50 per cent. There is no getting away from this proposition. Professor Fuchs, whose text-book is universally accepted as the ophthalmologists' bible, as well as Docent Carl Lindner, of the University of Vienna, both of whom I consulted in person in the matter, agree that 20/40ths represents 50 per cent. of normal and also that it is scientifically indefensible to inject considerations of peripheral vision or any other factor, in an attempt to minimize the loss of working vision represented by the formula 20/40ths.

The standard text-book on opthalmology to which I have referred says definitely: "If one eye sees an object of a given size at a given distance and a second eye sees the same object at twice the distance, then the visual acuity of the second eye is twice as great as that of the first."

In connection with this established scientific fact it may be interesting to quote an opinion of Dr. Weeks embodied in the Arcangelo case, where he says that "vision of 20/40ths at least is necessary to engage in the orderly vocation of life." I mention this merely to re-emphasize the manifest importance of 20/40ths, which some have tried to belittle to an inexcusable extent.

On the other hand, I concede that looking at the proposition from the standpoint of *industrial efficiency*, 20/40ths represent *less* than 50 per cent. impairment of vision. This is especially apparent when we are called upon by the Law to consider 20/100ths as equivalent to the loss of use of an eye. 20/40ths would now have to be assigned a new rating if the formula is to be brought into harmony with the principle of industrial efficiency by which 20/100ths was declared to be equivalent to loss of use of an eye.

We now have two fixed points to deal with: 20/20ths as representing normal working vision and 20/100ths as representing industrial blindness. The distance between the two points marks the range ascribed to industrial vision. If the intention is that the permanent partial impairments anywhere between the two points shall be rated in accordance with the relation of these impairments to the more or less arbitrarily fixed point of industrial blindness, we shall have to depart from the purely physical standard of rating and proceed along a new line which may be called *industrial efficiency*.

This change becomes necessary because *physical rating* proceeds in constant relation to *normality*, while *industrial rating* takes account of losses in their relation to the point of *blindness*. The latter point is of considerable practical importance and may explain why it is that physical rating and industrial rating of losses do not accord one with the other, generally speaking.

A reduction of vision from 20/20ths to 20/40ths represents a loss of 50 per cent. of normal visual acuity: Industrially the same loss does not represent 50 per cent. of the efficiency of the eye, when taking into consideration that 20/100ths is to be considered total loss of use of an eye. In other words, the physical losses up to and below 20/40ths do not represent a corresponding industrial depreciation.

An intelligent friend who has followed my former discussions of this matter has put the point in this way: "Reckoning from normal sight, impairment of industrial efficiency of sight does not keep pace with loss of visual acuity but drags behind up to a certain point; after that point is reached the loss of industrially efficient sight travels faster than loss of visual acuity."

With a view to finding a solution of the problem of how to rate visual losses occurring between 20/20ths and 20/100ths in a manner to preserve the principle of average justice, from the standpoint of industrial efficiency, I prepared a table some time ago. Arbitrary and mechanical as the table may appear, it does seem to assure an adequately fair rating. The point of industrial blindness having been fixed arbitrarily, the table itself must necessarily partake of the character of arbitrariness. The table is as follows:

	Loss		Loss
20/25ths.....	6¼ per cent	20/65ths.....	56¼ per cent
20/30ths.....	12½ per cent	20/70ths.....	62½ per cent
20/35ths.....	18¾ per cent	20/75ths.....	68¾ per cent
20/40ths.....	25 per cent	20/80ths.....	75 per cent
20/45ths.....	31¼ per cent	20/85ths.....	81¼ per cent
20/50ths.....	37½ per cent	20/90ths.....	87½ per cent
20/55ths.....	43¾ per cent	20/95ths.....	93¾ per cent
20/60ths.....	50 per cent	20/100ths.....	100 per cent

It will be noticed that, despite its mechanical character, the table solves a problem which has troubled fair-minded men considerably, and that is how to compensate more adequately the impairments in excess of what is physically a loss of the first 50 per cent. of normal vision. Economically speaking, the loss of the first 50 per cent. of working vision, implied by the formula 20/40ths, is not as serious as the losses beyond this point. In my table 20/40ths is rated as 25 per cent., leaving 75 per cent. to be distributed for impairments beyond to 20/100ths. The more I study the table, the more I feel persuaded that it meets the requirements of simplicity, common sense and justice.

It is possible that there may be need of a legal provision defining how permanent partial losses of vision shall be prorated, if there should be any doubt whether my table answers the purpose. Such a provision would have to be supplied by legislative enactment.

Now that the present paper has come to a close, it may be proper that I should indicate, in a few words, what relation it bears to my two former papers dealing with the same subject.*

In opening the question of how to rate partial impairments, my insistence was upon the fact that the Snellen test supplies the only universally accepted scientific standard for determining percentages of working vision. Concentration upon this point appeared necessary in order to counteract current indefensible arguments tending to minimize reductions of working vision.

In my second paper stress was laid on two principles on which visual impairments may be rated, to wit, the purely physical and the strictly economic principles. A "middle way" was suggested as a solution. This "middle way" is more fully discussed in the present paper as meeting more directly the conditions to be considered when we deal with eye cases *under the New York State Compensation Law*. The "middle way" suggests the principle of average industrial justice. This principle governs the legal provisions for permanent physical impairments. It is to this principle, therefore, that the rating of such impairments must conform.

*These papers appeared in the MEDICAL RECORD; the first in the number for May 14, 1921; the second in the number for August 6, 1921.

417 FRANKLIN STREET.

The Facial Paralysis of the Painter David.—The illustrious painter David is known to have suffered from this malady. It is even distinguishable in the painter's own portrait of himself in the Louvre. In the portrait by Langlois and in the marble bust by Rude, the palsy is very conspicuous, but, strange to say, affects the left instead of the right side. How could the sculptor and painter have made the same blunder? Could they have both followed a false memory in the absence of the living sitter? It is possible, but not probable. A more plausible explanation seems to be that the paralysis was really right sided and that when David studied his features in the mirror to transcribe them on the canvas he transposed the deformity to the wrong side. But this view has been pronounced inconceivable by La Fontaine.—*Le Progrès Médical.*

BLOOD CLOTTING AND THE CONTROL OF HEMORRHAGE.*

By C. A. MILLS,

CINCINNATI, OHIO.

(From the Laboratory of Biochemistry, University of Cincinnati Medical School and the Cincinnati General Hospital.)

1. *Introduction and Discussion of Theories of Clotting.*—The great part that hemorrhage plays in clinical medicine and surgery warrants a close study of the means of its control. And, since the clotting of the blood is by far the most important factor concerned in limiting this loss of blood, we will consider the practical aspects of the coagulation question.

It is not necessary for us to review here the various theories that have been advanced to explain the clotting process. They are far too numerous and complex for an article of this nature and may be found well summarized and discussed in text books of Physiology and Physiological Chemistry. We will, however, point out certain important differences that exist between these previous theories and the one used as the basis for our work.

Except for the views of Wooldridge and Nolf, clotting has always been considered to depend on thrombin formation in the blood and the subsequent transformation of the fibrinogen to fibrin by this thrombin. Calcium was considered necessary for the formation of the thrombin, and this process was quickened by tissue extracts. It was not known whether either the calcium or tissue material entered directly into the fibrin formation. Rather, it was thought that they took part only in thrombin production. Tissue extracts were considered by some to initiate thrombin formation, and by others to neutralize the antithrombin supposed to be present. No definite idea of the chemical action of any of the clotting factors engaged in the process was put forth, so that the problem remained hazy and indistinct in spite of all the various theories.

Wooldridge[1] had a much simpler idea of the process. He considered that there were two substances in the blood (*a*-fibrinogen and *b*-fibrinogen) which united to form fibrin whenever the blood was withdrawn from the vessels. The active substance of tissue extracts he found to be similar in composition and action to his *a*-fibrinogen. Any of these fibrinogens that were present when clotting occurred he found bound in the fibrin produced. Each fibrinogen was found by him to be a protein phospholipin compound, the phospholipin being an essential factor in the clotting process. At the time of his death, however, he had not arrived at a clear idea of the chemical nature of the fibrinogen interaction and fibrin formation. Thrombin he considered an end product of the process, coincident with fibrin. He knew nothing of the importance of calcium at that time.

2. *Theory upon Which Our Work Is Based.*—Using Wooldridge's work and ideas as a basis we have arrived at the following view of the clotting process: *Tissue-fibrinogen* (thromboplastin, thrombokinase) the active principle of tissue extracts, is a protein phospholipin compound probably consisting of about 13 phospholipin molecules united to one protein molecule, the union very likely being through the amino groups of the phospholipin molecules and carboxyls of the protein. This leaves an ionizable H^+ (or Na^+) on the phosphoric acid of each phospholipin in the tissue fibrinogen molecule and causes the latter to be negatively charged in neutral solution. *Blood fibrinogen* is also negatively charged in neutral solutions, which means that it, too, ionizes off H^+ (or Na^+) ions. When these two fibrinogens are present together in solution in an ionized state and soluble calcium salts are added in proper amounts, fibrin formation occurs by a replacement of two H^+ (or Na^+) ions (one on the tissue fibrinogen and one on the blood fibrinogen) by a Ca^{++} ion. Thus the two fibrinogens are united into large complex molecules which possess a low solubility and the power of gelation. This fibrin formation is thus analogous to the precipitation of other negatively charged colloids by bivalent metals.

Just as calcium ions are essential for the union of these two fibrinogens, so also is the phospholipin of the tissue fibrinogen. Extraction of this phospholipin by benzene at room temperature, so as to leave the protein fraction soluble, prevents the fibrin formation almost as effectively as does the lack of calcium. Restoration of the extracted phospholipin enables the clotting to proceed. Both the calcium and phospholipin are to be found in the fibrin produced, a part of the phospholipin being impossible of extraction by boiling lipoid solvents whereas, before union had taken place, it was readily extractable by benzene at room temperature. (The evidence in favor of this view of clotting is to be found in a recent paper by C. A. Mills and George M. Guest.[2])

3. *Clotting as a Physiological Process.*—Looking at blood clotting as a physiological process, then, we find that it has become well adapted to fulfil its function to the body, that is, to prevent undue loss of blood from ruptured vessels. The circulating blood contains very little tissue fibrinogen, so that it is able to remain fluid and still contain soluble calcium salts and blood fibrinogen. However, in event of tissue injury with rupture of blood vessels, the escaping blood is immediately mixed with tissue juice and clotting induced. It has been found that those tissues in which hemorrhage is most dangerous possess the richest stores of tissue fibrinogen, so that bleeding there is most quickly controlled. Such tissues are the brain, lungs, kidneys, and the endothelium of the blood vessels. Not only does the escaping blood clot quicker when mixed with the juices from these tissues, but the amount of fibrin formed is much greater and the texture more firm. The additional strength thus imparted to the fibrin plug filling in the opening renders subsequent rupture at that point less likely. The fact that the tissue fibrinogen forms an integral part of the cell cytoplasm, and that the fibrin formed is thus practically continuous with the cell structure also insures a firm anchorage for the fibrin network.

There exists one apparent contradiction to this

*This paper is in the nature of a summary of the work on blood clotting carried out by the author with the aid of George M. Guest, Stanley Dorst, Stewart Mathews, R. N. Speckman, George C. Mynchenberg and Dr. Moritz Petersen. Some of this work is as yet unpublished, but will appear soon.

view of the clotting process as a well adapted protective mechanism. Surgeons everywhere will testify to the seriousness of wounds in the liver substance and the difficulty of controlling the hemorrhage. One would expect to find laid down in the liver cells a very rich supply of tissue fibrinogen, so that the great capillary bleeding in wounds here might be readily controlled, as is the case in the lungs, brain, and kidneys. Actually we do find more of the substance in the liver than in any other tissue. It has the same appearance as that from the lung, but is almost entirely devoid of coagulative action. This is due to the phospholipin fraction, since if its phospholipin be removed by the use of benzene at room temperature, and that from the lung compound substituted for it, then an active coagulant results. Apparently the protein fractions of the lung and liver compounds are similar, the difference being in the nature of the phospholipin. There has been no suggestion put forth yet as to why this difference should exist, leaving the liver but poorly protected against extensive loss of blood through inability to bring on rapid clotting.

4. *Means of Reinforcing the Clotting Mechanism.*—It is evident, then, that the body has a remarkably well adapted mechanism for controlling hemorrhage. However, there are times when we find this normal mechanism insufficient and wish to reinforce it. In such cases, what means should we use? What method would be more in harmony with the plans of nature than merely to increase the amount of tissue fibrinogen to be mixed with the escaping blood? And this all the more since this substance is the strongest blood coagulant known. In this way no foreign material is introduced into the clot and the transformation into scar tissue should proceed most rapidly. These facts have been recognized for several years in the use of brain extracts for local application, although the true nature and manner of action of the active principle was unknown. It was thought that the cephalin of the tissue extracts was responsible for the activity, so this substance was used to some extent as a hemostatic, but with little success.

The addition of further tissue fibrinogen to the escaping blood is advisable, but it should not be added in the form of crude tissue extracts because these contain in addition albumins which are toxic to the body. It has been shown[3] that tissue fibrinogen has no toxic effect on the body unless clotting of the blood is induced. The albumins, however, possess a histamine-like action in every case and are quite toxic. The use of the purified substance is therefore indicated, especially since its ease of preparation renders it almost as accessible as the crude extracts. We have found the clotting process to be very similar in different species of mammals, so that we may use the tissues of other mammals (such as sheep or calf lungs or brains) in preparing the tissue fibrinogen for use in clotting human blood. In our own experimental work we have found that the lungs yield the most potent product and that this is capable of greater activation to increased effectiveness by cephalin addition than is brain extract. This activation by cephalin was described in a previous publication.[4]

5. *Indications for a Reinforcement of the Clotting Process and Methods to Be Used.*—We have yet to consider the conditions that call for a reinforcement of the clotting mechanism of the body. The one most frequently met with is, of course, hemorrhage from an open wound whether accidentally or surgically inflicted. Here the need is for the strongest and most concentrated coagulant preparation possible, since it is bound to be diluted by the outcoming blood. The flow of blood should be checked as much as possible while applying the coagulant so that the fibrin plugs may extend well back into the ends of the ruptured vessels. What is desired is clotting in the quickest possible time with the formation of a firm, well anchored fibrin plug. The effect here is purely local, practically none of the coagulant being absorbed from the raw surface.

For hemorrhages that are not accessible for local application of the tissue fibrinogen recourse must be had to a different method of treatment. We have tested out the effects of intraperitoneal and subcutaneous injections of the coagulant on rabbits, dogs and rats, and find that the clotting time of the blood may be greatly shortened with apparently no danger of intravascular clotting. The blood becomes so readily coagulable that it is difficult to obtain a sample of blood from a rabbit's ear for testing. *Great care must be exercised, however, to avoid injecting the substance directly into the circulating blood as there is very great danger of immediate death from intravascular clotting.* We are now engaged in testing out the possibility of rectal adminstration in order entirely to avoid this danger and also to eliminate the necessity for a strictly sterile product. This systemic effect from internal administration would be particularly adapted to concealed hemorrhages and post-partum bleeding following childbirth. It might also serve a very useful purpose if given just before surgical operations, as the blood would thus be rendered much more coagulable and the oozing of blood onto the field would be considerably lessened.

The last and most interesting condition in which tissue fibrinogen will probably prove of value is hemophilia. The true cause of this condition in certain individuals is unknown, but it is very suggestive to note that in all cases this blood clots as well as does normal blood when tissue extracts are added to each. Whether the tissues of the hemophiliac individual are devoid of active tissue fibrinogen so that the escaping blood fails to receive this stimulus to coagulation, is a question that can be answered only when such tissues are obtained for examination. So far we have not had this opportunity. We are now engaged in trying out the internal administration of the coagulant to hemophiliacs in the hope of reducing their clotting time at least to within the limits of normality, and lower if possible. If this is accomplished, then surgeons need not fear to operate on these individuals when the need arises. A preliminary treatment with the tissue fibrinogen and a supply on hand for local application should render such operations safe so far as hemorrhage is concerned. Furthermore, the internal hemorrhages to which these patients are at times subjected, should respond in like fashion to the treatment with the coagulant internally.

THE NEUROPATHOLOGY OF NEURASTHENIA.

By GUSTAV F. BOEHME, Jr., M.D.,
LOS ANGELES, CAL.

THE title of this paper is probably misleading in that the purpose of the article is rather to point out what is not neurasthenia, and how processes simulating this syndrome can be separated therefrom. When Beard first described this disease he specifically drew a picture of "nerve fatigue," and subsequent workers in the field have consistently held for this definition. Yet the medical profession and the layman have made it the rubbish heap for neurological processes that they did not understand, or for the various neuropsychic manifesations that did not fit into definite diagnostic pigeonholes.

True neurasthenia must be limited to true nerve fatigue, the cardinal symptom of which is weakness, both in the psychical and physical fields. It can be sharply divided into two great groups: (1) Acute Neurasthenia, and (2) Chronic Neurasthenia.

The former type comes on suddenly as the result of some severe trauma, physical or psychic, upon an individual who is of neuropathic makeup, usually of an hereditary type. Given such an individual, let us suppose that he sustains a severe trauma, especially one in which he has time enough to see the oncoming catastrophe, or let him be suddenly subjected to a severe bereavement, or some great financial loss or other psychic trauma, he collapses, great psychic and physical weakness ensues. He complains of headaches, his thoughts will not follow his logical commands, there is great muscular weakness, ideomuscular reactions are abnormal. He says he is tired, that he cannot do things. This is the true picture of neurasthenia and must be sharply and definitely separated from the picture of a neurosis. What has occurred in such a case? What is the pathologic picture? It is impossible to state definitely, but the following hypothesis will explain the clinical symptoms present: The individual has an unstable neural balance, the synaptic relation between cells is extremely delicate, of a hairspring trigger type. The cells themselves are highly irritable. In every day life these individuals are recognized as eccentric and peculiar. Comes the sudden trauma, and with it comes the dissolution, temporarily, of delicate synaptic relations, comes a destruction of Nissl's substance, a loss of the material upon which depends all neuroreaction. The result is the development of misdirected impulses, due to the transmission of impulses along new and unguarded pathways. The great weakness is the direct result of destroyed Nissl's substance.

Chronic neurasthenia, on the other hand, is of slower onset. The symptomatology is the same but more gradual in occurrence. Fatigue, great muscular weakness, insomnia are the cardinal symptoms. It is the result of a steady strain continuing over a period of time upon a neuropsychic personality. Pathologically the picture is the same as in the former condition, but the disturbance in synaptic relation and in cell chromatolysis is less sudden and less complete. The outlook is better and under proper treatment one can say, as I have frequently heard Starr state at his clinics, that sooner or later cure is complete.

With this conception of neurasthenia clearly before us, that of "nerve fatigue," let us then examine the various processes that have masqueraded, and still masquerade under that name.

In my own experience the various neuroses are most frequently mistaken for this process. The subject of an anxiety state, of a latent dread, of an unfulfilled wish, all those individuals who suffer from sexual abnormalities, from misplaced affections, and who develop peculiar physical trends, who state that they fear this, that, or the other thing, who cannot sleep, who believe they are being misused by the world, have in my experience been labelled "neurasthenics" when there has never been any neurasthenia present. With these individuals there has been a struggle between the subconscious and the conscious, between the wished for thing and the actuality, and being of poor nervous balance they have succumbed, to a degree, in the struggle. A rather characteristic difference between these individuals and the true neurasthenics is that despite their symptoms they are always able to take care of themselves, in fact are solicitous about their welfare, while the true neurasthenic is too tired to care, he is really ill; the other individual wishes to be ill. There is only one solution for these patients, the mechanism of their condition must be made clear, they must understand it, and once and for all conquer the subconscious desire by a true appreciation of the realities of life. In true neuroses this can, with patience, almost invariably be accomplished.

The failure to cure such a neurosis by the methods suggested should lead the practitioner to seek for other causes that may be at work to the detriment of the patient. Chronic infection should be the first thought. I have seen many mild neuroses kept alive by mild oral sepsis, or, in my own experience more frequently, by a chronic intestinal morbid state. Constipation and intestinal fermentation are frequent. In many cases there is a definite indicanuria present. It is surprising to witness the improvement of these patients under wisely chosen catharsis and hydrotherapy. Opening the emunctories seems to open up mental paths and lead directly to cure.

Again definite physical processes should at all times be examined for. A mild, early tuberculosis is frequently mistaken for neurasthenia. I have seen pernicious enemia, early malignant processes, visceroptosis, and other true physical conditions under treatment for neurasthenia until beyond relief by medical attention and aid.

Thyroid conditions and other endocrine disturbances should never be forgotten. Adrenal asthenia (which I note is now included under the title neurasthenia by careless endocrine workers) is a definite entity, characterized by low blood pressure,

pigmentation, muscular changes, dermatographic changes, and definite reactions to endocrine and blood sugar tests. Early thyroid malconditions can be demonstrated by adrenalin, atropine, and pilocarpine tests associated with studies in basal metabolism. In no instance of socalled neurasthenia should these investigations into the endocrine conditions be neglected. With these examinations a careful study of that system so closely allied to the endocrine, the vagosympathetic, should always be made.

Again the hydraheaded syphilis must not be forgotten. It is truly surprising how often the earliest manifestations of paresis simulate true neurasthenia, and in no instance should the physician be satisfied to make such a diagnosis without a Wassermann test and, if necessary, an examination of the cerebrospinal fluid. I have on a number of occasions been consulted by the members of a patient's family, who told me he was losing a hold on things, that he had severe headaches (especially at night, a very important point), and marked insomnia. They also informed me that he has been overworking, and yet I found a definitely positive Wassermann with early sluggish pupils.

And finally many early psychoses simulate to the uninitiated, neurasthenia. Dementia precox, the depressive phase of manic depressive insanity, rarely the early stages of paranoia, are all mistaken for this disease. But this would not be so if one remembered always the cardinal syndrome, nerve fatigue—not peculiarity of personality, not irritability, not flightiness or other pyschic manifestations. If the picture of neurasthenia is kept clearly in mind, every other type of condition that might simulate it will arouse suspicion just because of the fact that it is different, and so lead to the proper diagnosis.

To sum up, therefore, the following suggestions are offered: (1) Neurasthenia is a definite entity, and must be limited to "nerve fatigue." (2) Many processes are mistaken for it, the most important of which are neuroses, chronic infections and intoxications, true physical disease in its incipiency, endocrine conditions, neurosyphilis, incipient psychosis. (3) Laboratory examinations are essential to the diagnosis. Urinary examinations may reveal chronic intoxications or nephritides. Blood examinations may show infection, lues, or blood sugar and other changes. Cerebrospinal fluid examination may reveal early neurosyphilis.

THE ADRENALS AND THEIR RELATIONSHIP TO THE PSYCHE.

By LEON VINCENT KEAR, M.D.,

OYSTER BAY, N. Y.

Physical manifestations of a positive nature are no doubt the most convincing evidence which can be presented to the inquiring or skeptical mind. Those of us who have been carrying on as regards endocrine therapy have this convincing evidence presented to us in those various gradations of hypothyroidism which have been treated with thyroid extract and in like manner with those cases of hyperthyroidism which have been treated with ovarian extract. The reduction of constitutional obesity is one of the most striking examples of the former, while the subsidence of the physical phenomena of hyperthyroidism has been well demonstrated in the use of ovarian extract in this latter type of case.

However gratifying the results obtained in endocrine work from a physical viewpoint, let us not in our enthusiasm fail to consider the equally amenable and important psychic aspect of what is proving itself to be the new "Path to India" in our heretofore puzzling clinical pictures which have been tagged neurasthenia, hysteria, and the like, buffeted from one doctor's office to the other, misunderstood, unrelieved, and in many cases becoming at length the victim of the wiles of quackery.

Empiricism has been sent to the guillotine by modern medicine and it is fitting and proper that it should be, yet in the absence of demonstrable facts when we are lacking those definite conclusions so essential as guide posts, are we not compelled by circumstance to recall the empiric shade and follow it into new fields of endeavor where proofs are obtainable only through the resulting response to therapy? That the psychic effect of endocrinology is empiric is an acknowledgment I readily make, yet who can deny in the face of the conclusive evidence that this empiricism is not warranted?

Familiar to all are the nervous phenomena associated with the over active thyroid, conclusive the most skeptical will grant of the intimate relationship of this gland to the nervous system. Is it not quite as logical to conclude that the other endocrines bear a like relationship to the nervous system and the psyche? Assuming that such is the case, and with particular attention being paid the adrenals, I have treated a series of cases with desiccated extract of adrenal cortex with the express purpose of determining whether or not that which is so theoretically sound from the psychic aspect of endocrine study would prove itself therapeutically so when put to the test in those cases so commonly labelled as nervous type, neurasthenic, hysterical in which the prevailing symptom was a marked emotional upset persisting over varying periods of time.

The striking feature of these cases is their similarity of symptomology—fear, depression, obsessions and a general tendency to self-subjection, all of which are associated with adrenal function, characterized each patient. I will cite only those cases in which I believe the most striking results were obtained.

Case I.—D. O. was a girl of twenty who had concluded that the world held nothing for her, but who hesitated at suicide because of the moral aspect of the act. She was extremely pugnacious and captious, evidence of which she displayed during the taking of her history, resentment being shown at each new intrusion into her affairs. She was easily excited, extremely irritable, and given to fits of depression. Life was a fearsome existence to this girl; at one time it was the dread of physical infirmity, at another the fear of insanity; her attitude toward those about her was one of negativism, she harbored fancied grievances against those with whom she was closely associated, and was entirely lacking in assertiveness and self confidence in dealing with the same. An atmosphere of negative self feeling predominated her psyche and at the time she consulted me she had had the "blues" for the three preceding weeks. Her mental state had been of this trend for the past two years and various types of therapy had afforded her no relief.

The physical examination of this patient revealed nothing except a blood pressure which varied at each new reading, being sometimes high and again very low. She complained of some gastric distress of a vague nature. Her thyroid appeared slightly enlarged and a faint exophthalmos was discernible. The pulse was 101. The chest and abdomen were negative. The reflexes were normal. The blood revealed no abnormalities and the blood Wassermann was negative. The basal metabolism was not determined.

On April 1, 1921, the patient was placed on ovarian extract, gr. 5, and suprarenal extract, gr. 2, t.i.d. Milk of magnesia, drachms 2, night and morning was given to regulate the bowels. It was explained to her that her psychic irritation was due to the action of glands and she seemed to feel satisfied to some degree that her life problems could be solved if this could be corrected. She was instructed to report in one week's time.

On April 9 there was quite a noticeable change in the patient's mental attitude, as she expressed she seemed to have a better grip on things. Her obsessions seemed greatly allayed and she slept better and felt improved physically. Suprarenal extract, gr. 3, was given alone and the marked improvement of her blood pressure commented on.

On April 23, the patient called and her very entrance into the office heralded her changed mentality. There was the evident expression of good will and confidence of the well balanced individual and throughout her conversation an entire lack of irritability or depression. I congratulated her and she beamed gratitude in response. The same therapy was continued.

June 1, 1921. At the present writing the patient is enjoying more contentment of mind than in several years. She expresses and conducts herself in a manner approaching the norm of positive self feeling. She is now employed as a clerk and is carrying out her duties in a most satisfactory manner.

Case II.—M. D. was a girl of eighteen who consulted me complaining of nervous spells which she had at frequent intervals. She was rather a nominalist than a realist and was given to introspection and retrospection with a strong penchant for poetry and the allied arts. Her greatest annoyance was the fear of physical harm which was greatly exaggerated when she was in a crowded gathering of any nature. The sex instinct was well developed and she was of the gregarious type. The patient dreamed a great deal and her dreams were of a fearsome nature, well remembered and written down in a lucid readable manner when brought to me. Intellectually she was beyond the average. Spells of depression were frequent and usually followed one of her nervous spells.

Physical Examination.—Weight 108 lbs. The teeth were in good condition and the throat negative. The thyroid was evident to the eye and easily palpable on swallowing. The heart was normal in contour and rythm, but was accelerated in rate, the count at the apex being 112 per minute. The abdomen and extremities were negative and the reflexes normal. The pulse rate was 110, and the blood pressure S. 120, D. 90. The urine and the blood Wassermann were negative. The Goetsch test was positive. The basal metabolic rate was undetermined.

Diagnosis.—Thyroid +, Adrenal —.

On April 15, the patient was given ammonium bromide, gr. 10, t.i.d., and seven grains of desiccated suprarenal gland combination with three gains of ovarian extract, t.i.d., and instructed to return in one week.

April 22. The patient sleeps decidedly better and her dreaming is in no wise as bothersome as heretofore. She says she feels more like doing things than before. The pulse is 88 and the count at the apex 94.

June 13. During the interim the same therapy was continued except that after the third week the ammonium bromide was discontinued. The patient's psychic manifestations have entirely disappeared, and no more striking evidence of the change in mental attitude could be illustrated than the fact that she now commutes daily to New York and is unaffected by the crowded conditions prevalent in the public conveyances of the city.

Case III.—A. P., age 43, consulted me because of dreams of a terrifying nature. Her history revealed domestic incompatibility and a distinct aversion to sexual relation with her husband. She was extremely irritable and given to fits of depression. She disliked company, but was fond of children and expressed great disappointment at not having any.

Physical Examination.—The teeth were in good condition and the throat was negative. The thorax and abdomen were negative. Neurological examination revealed no abnormalities. Blood pressure, S. 149, D. 90. Laboratory Examination.—The urine and blood Wassermann negative. The Goetsch test was negative.

Therapy.—An explanation of her condition was made on an endocrine basis. The patient was put on desiccated extract of suprarenal glands, gr. 5, t.i.d., and in a period of three weeks has had complete amelioration of symptoms.

Conclusions.—1. A marked emotional upset is often associated with under activity of the adrenals.

2. Our psychic manifestations of the subconscious are in a like manner closely allied with the suprarenals.

3. Associated with these under active suprarenals there is often an over active thyroid and that condition is readily remedied by administration of ovarian extract.

4. These patients benefit greatly when an explanation of their condition is made on an endocrine basis.

5. We are justified in laying down the foregoing hypotheses and treating this type of patient on an endocrine basis.

Comment as to controls, suggestions, and coincidence has been omitted. It reads as follows:

In some of these cases it may appear that adequate and rigid controls were not maintained or that suggestion as well as mere coincidence was not ruled out. However, I believe that the previous therapy could as well act the part of controls as any others that might be established, and as for suggestion the psychotherapist had his inning with two of the cases described.

Medicolegal Notes.

Medical Expert Should Not Testify to Fact, But Opinion Merely as to Cause of Condition.—A medical witness in a personal injury case, who had cared for the plaintiff immediately after the accident and regularly attended her professionally thereafter for some months, was allowed by the trial court to testify not only that the nervous condition which he discovered could be caused by the blow the plaintiff received, but also that he believed it was produced by the accident. The Michigan Supreme Court has held in various cases that the proper question as to cause of conditions found by a physician was what might have caused them rather than what did cause them, because the latter is a question of fact for the jury, but it has also held, in People v. MacGregor, 178 Mich. 436, 144 N. W. 869, that the distinction is in many cases of doubtful significance. In the present case, it was held of little importance, as the error in admitting the testimony, if any, was not reflected in the verdict.—Cord v. Pless (Mich.) 184 N. W. 427.

Applicant for Life Insurance Suffering from Influenza Held Not in "Good Health."—An applicant for a life insurance policy contracted influenza on the day before the policy was placed in the mails and, before the policy was received, died from pneumonia resulting from influenza. It was held, in an action on the policy, that he was affected with a serious and dangerous disease, which directly contributed to the immediate cause of his death, and therefore, at the time the policy was placed in the mails, was not in "good health" within a policy condition of delivery during applicant's "good health."—Denton v. Kansas City Life Ins. Co., Texas Civil Appeals, 231 S. W. 436.

MEDICAL RECORD.

See fourth page following reading matter for Rates of Subscription and Information for Contributors and Subscribers.

New York, January 28, 1922.

THE BRITISH MEDICAL SERVICES IN THE WORLD WAR.

IN the issue of the MEDICAL RECORD for January 7 editorial notice was given of the appearance of the first printed volume of the history of the Medical Department of the United States Army in the World War. There has now been published the first volume* of the Medical Services of the British Army in the same conflict. It is impossible to make any comparison of the two volumes, other than as to size, paper, and other physical properties, because "Army Anthropology," the first volume (not the first in serial number, but the first to be printed) may be said to be technical, whereas the first of the British history (the first in serial number as well as the first to be printed) deals with matters of administration. It comprises 463 pages, including the 356 pages of text, 82 pages of appendices, and 22 pages of index. There are twenty maps, charts, and other illustrations. Because of the character of the paper used for the text, the illustrations are all "inserts." The book is bound in dark green cloth, with back imprint in gold. The full page of abbreviations encountered in the beginning confirms the fears of one who has read other war books emanating from the medical department of the British army, that many of the pages will be found dotted with capital letter abbreviations.

We are reminded in a recent review of two monographs prepared, one by the Historical Branch, War Plans Division, General Staff, and the other by the Statistical Branch, General Staff, and recently published by the United States War Department, the London *Times*, Literary Supplement, incidentally notes the fact that these two branches of the General Staff have no counterpart in England. This being true, those who compile, or prepare for printing, the record of Great Britain's part in the World War are not confronted with certain of the difficulties which the editors of "The Medical Department of the United States Army in the World War" have to deal in the matter of citing documentary evidence of all data, and of keeping the history as nearly impersonal as is commensurate with historical clearness and accuracy. For, as stated elsewhere (MEDICAL RECORD, January 21, p. 130), all of our War Department histories, that of the Medical Department included, must conform to certain requirements of the General Staff. However, we are told in the preface to the present volume that more than 38,000 war diaries, numerous reports from commands at home and overseas, and voluminous administrative medical files from the theaters of war, were registered and filed, and the various subjects and documents containing references to them were indexed in order to facilitate the writing of the history from the available material.

The preparation and scope of the history had to be limited to meet the Treasury conditions, and so only twelve volumes are being prepared. These are apportioned as follows: General History of the Medical Services, four volumes; The Diseases of the War and the Medical Aspects of Aviation and Gas Warfare, two volumes; The Surgery of the War, two volumes; The Hygiene of the War, two volumes; Pathology and Medical Research During the War, one volume; The Medical Statistics and Epidemiology of the War, one volume. The volumes of the general history are written in narrative form, giving the chief features of the medical services in the United Kingdom, in garrisons overseas, and with the expeditionary forces in the various theatres of war during the years 1914-1918, and during any subsequent period in which war incidents of historical interest or importance occurred.

The present volume, the first of the twelve which it is proposed to issue, deals with the medical services in the United Kingdom and in garrisons overseas, with an account of the medical services in the operations against the German colonies in West and Southwest Africa and in Tsingtau. The remaining volumes of the general history will deal with the medical services in France and Italy, in the Mediterranean theatres of war, and in Mesopotamia, Aden, East Africa, and Russia.

It is safe to venture that the part of this volume which will receive the closest study constitutes the first twelve chapters, which deal with the preparation of the Army Medical Service for war organization; personnel and training; mobilization and administration of the medical services; hospital accommodation in the United Kingdom; the reception, distribution, and disposal of sick and wounded in the United Kingdom; the medical examination of recruits; the recruiting and training of personnel for the Medical Services; the supply of medical and surgical equipment and stores; sanitary organization in the United Kingdom; the organization of voluntary aid; demobilization.

The feature which stands out most prominently in the history of the medical service, we are told,

*History of the Great War Based on Official Documents, Medical Services, General History, Vol. I. Medical Services in the United Kingdom; in British Garrisons Overseas; and During Operations Against Tsingtau, in Togoland, the Cameroons, and Southwest Africa. By Major-General Sir W. G. MacPherson, K.C.M.G., C.B., LL.D. His Majesty's Stationary Office, 1921.

is the magnificent and harmonious cooperation afforded by the medical profession throughout the Empire, and by a host of voluntary and other helpers in the work of the Army Medical Service and the Royal Army Medical Corps. "A history of the medical work in the war becomes, therefore, a record not only of the medical services of the regular army, but of all those who worked in it and with it."

SO-CALLED IDIOPATHIC SPLENIC HYPERTROPHY.

By the term idiopathic hypertrophy of the spleen is meant any hypertrophic process primarily arising in the spleen and without any of the usual causes for enlargement of this organ being present. The process usually remaining localized to the spleen, follows a progressive evolution and presents a variable histological structure. Besides the numerous splenomegalias developing during acute or chronic infections such as typhoid, tuberculosis, leucemia, or paludism provoked by cystic or cancerous degeneration, or resulting from a toxic or infectious process of the liver or long standing heart disease, there is a class of chronic splenic hypertrophies—truly idiopathic in nature—having none of the usual etiological factors and whose pathology is still hypothetical.

The external characters of splenic hypertrophy are to be counted among the most characteristic elements of these tumefactions. From the outset the clinician's attention is drawn to the abdomen on account of its deformity, its large size, with broadening of the lower part of the thorax and the development of collateral circulation. The spleen usually acquires considerable proportions; in one case the organ was twenty-seven times its normal weight and size, in others twelve to sixteen times. The spleen occupies the entire left side of the abdomen, passes beyond the umbilicus and often reaches the iliac crest, projecting above the pubic symphysis. Palpation shows that the tumor is firm and resistant with the characteristic notches of the anterior edge of the organ. The area of splenic dullness is easily made out because there is never any ascites at any phase of the process. The liver progressively hypertrophies as well, although in a lesser degree, filling the hypochondrium and occasionally part of the right flank. The integuments are covered by venous arborisations due to circulatory disturbances from compression, the umbilicus projects, the base of the thorax broadens, and the epigastric hollow is effaced. The respiration becomes upper costal in type. The lower limbs are often large, edematous and painful, and frequent cramps are complained of. As the splenic tumefaction develops, serious disturbances of the general health are noted. There are first anorexia, dyspeptic phenomena, and vomiting, followed by loss of strength, difficulty in breathing, palpitations and other cardiac phenomena; the pain at the onset is dull but increases in intensity and occurs in paroxysms excited by walking or fatigue, with irregular quiet intervals during which the patient feels astonishingly well.

The essential characteristic symptoms of this form of chronic splenopathy are, besides the peculiar hypertrophy of the organ, absence of enlarged lymphnodes in all the regions accessible to clinical exploration; the absence of leucemia, the blood examination during the various phases of the process never showing any notable increase of the leucocytes; the red blood corpuscle anemia without changes in the red cells or nucleated cells, and lastly the absence of any peritoneal fluid collection. Besides the consecutive hypertrophy of the liver there are other more contingent signs. In the first place there are hemorrhages, the earlier and most persistent being epistaxis, which is sometimes very severe. Later on, cutaneous hemorrhages occur in the form of purpuric or ecchymotic spots on the legs, while on the face they appear as fine specks more or less confluent. The gums quite frequently are softened, becoming fungous as in scorbutus, bleeding readily and rendering mastication both painful and difficult. A slight or even marked icterus is met with when the liver has become hypertrophied; it is usually only temporary and only gives rise to a pale yellow tint of the skin and conjunctivæ, without bile salts in the urine. Fever is uncommon, but when it exists it indicates some intercurrent affection, such as pleurisy or tuberculosis.

The evolution of the process is progressive and generally slow. The general health remains relatively quite good for some time, slowly declining with the progress of the affection. The normal functions of the various organs are interfered with; the cardiac and respiratory symptoms becoming marked at the same time that the dyspepsia and diarrhea occur. Cachexia or some intercurrent affection carries off the patient. Splenectomy is the only treatment that offers any chance of prolonging life and ridding the patient of his sufferings.

THE POSSIBLE TOXIC ACTION OF RENAL EXTRACT.

Renal opotherapy by subcutaneous injections has been discarded on account of its unfortunate action on the kidneys, and exhibition by mouth seemed to have been preferred until Carles and Michel stated that they had been able to produce nephritis by this means. The untoward results reported by these observers were, however, based upon experiments made under the most unfavorable conditions and consequently should not be accepted. These observers gave guinea-pigs macerations of guinea-pig kidneys and found that the animals developed an epithelial nephritis in about ten days. Now, it is a defective method to administer kidneys to animals when the organs are derived from their own species, while the choice of an herbivorous animal like the guinea-pig is most unfavorable for the study of the action of a carneous maceration, because it may be questioned whether it is the renal tissue itself

that possesses the nephrotoxic properties or the meat alone that produces renal lesions in certain herbivorous animals.

To elucidate this question Arquembourg (Thesis, Lille, 1917) fed a guinea-pig on horse-flesh mixed with the usual food. During the first month the animal's weight remained about the same and its general condition seemed excellent; then, at the end of five weeks albuminuria occurred. The animal then lost weight very rapidly and was killed during the sixth week in order to remove the kidney in the best condition for a cytological examination. Microscopical examination of the pig's kidneys affirmed the existence of pathological lesions. In the glomerular zone, the dilated capillaries increased the size of Malpighi's corpuscles, while in the intertubular connective tissue zones, the capillaries and especially the tubuli contorti presented an appreciable dilatation. The tubuli themselves were the seat of manifest cytological lesions; the epithelial cells did not line the walls regularly and in places the epithelium was completely detached; elsewhere a protoplasmic mass was found representing the dimensions of three or four cells completely deprived of nuclei. Granular protoplasm filled the lumen of some tubuli and its irregular arrangement revealed large vacuoli simulating a network of fine meshes. Briefly, these were lesions of interstitial nephritis provoked by the simple ingestion of meat. It is therefore an error on the part of Carles and Michel to attribute toxic properties to kidney substance, because these properties are common to all kinds of meat ingested by guinea-pigs.

The experimental study of the toxicity of the maceration for the kidney should therefore be made in omnivorous or carnivorous animals. Arquembourg selected dogs for this purpose and gave enormous quantities of renal extract to them. Now, after repeated daily absorption of doses proportionally from seven to twelve times those usually given to man, none of the animals developed albuminuria or disturbances of the secretion of urine.

In subjects with nephritis it may perhaps be admitted that renal extract is susceptible of aggravating already existing renal changes, but in none of the subjects to whom opotherapeutic renal products have been given has any aggravation been noted; on the contrary, a decrease in the albuminuria is usually observed. The possibility of toxicity of pig's kidneys in the case of certain renal lesions cannot be absolutely denied, but it is safe to affirm that this is the exception and that in the generality of cases renal extract has not a nephrotoxic power. Nevertheless, the fact that pig's kidneys eaten as food do not ordinarily provoke or aggravate a nephritis should not lead us to conclude that they are devoid of toxicity for the organism; because renal extract, like all active medication, should be maintained in doses not exceeding certain limits, otherwise accidents are prone to arise. All those who have employed maceration of kidneys have noted gastrointestinal accidents after a certain dose has been exceeded or from too prolonged absorption of the product.

Renaut, the promoter of the method, recommends that the medicament be not given for more than ten days in succession and that there be an interval of rest for five days between each series of ten-day exhibition, otherwise after a time accidents of variable gravity will occur, such as perspiration with an odor of urine, papular or miliary cutaneous eruptions, and gastric disturbance with nausea and vomiting.

REDUCTIVE ANALYSIS.

IN his entertaining novel, "If Winter Comes," Mr. Hutchinson draws a character, Mr. Fargus, who will long be remembered by his readers. Aside from his eccentricities and those of the remarkable household of which he was the nominal head, Mr. Fargus had one pet idea which falls in line with the modern trends of dealing with the psychoneurotic and psychotic patient. When a misadventure happened to him, when he ran into a snag in the current of his daily life, or when things went suddenly wrong, he would begin at that point and retrace events, holding that just as each event was the logical result of everything which had preceded it, the occurrence which had been unpleasant or disastrous must have been the result of a divergence at some particular point from the straight and desirable path.

And is not this what we try to do with those of our patients whose pathology lies in the psychic sphere? We have, let us say, such a patient who has gotten into an emotional jam; he quarrels with his wife, his employer is down on him, his fellow employees ridicule him, and he has thoughts of suicide. Ten years ago, it may be, such a one was newly and happily married, his business relations were pleasant and stimulating, and he sang as he shaved in the morning. Through what concatenation of circumstances did he arrive at his present plight? To discover this we must go back step by step over the emotional life of the patient. We cannot, of course, assume that even in that superficially carefree time of ten years ago there were no indications of approaching trouble. We must go back further still, to his boyhood, to his infancy, and trace the course of his psychic development. What methods of adjusting himself to his environment did he work out during his most plastic and formative years, and why were they unequal to later demands upon them? In short, we must do what might very well be called a reductive analysis. When we have discovered where lies the inadequacy we can turn our attention to the problem of readjustment.

It is all very much like the cynical attitude of Mark Twain's Mysterious Stranger. If the gate had not been left unlocked, the child would not have wandered out to the river and been drowned, but on the other hand he might have lived to become a murderer and break his mother's heart by

some more refined cruelty. Life is made up of a multitude of little events, acting and reacting upon each other. Change one of these ever so slightly and two others are changed. These in turn alter four more, then eight, soon several hundred, and with the passage of a little time the careers of individuals and the histories of nations are written otherwise.

But with all such far-reaching consequences our psychological analysis has but little to do. We can not alter, even if we would, the pattern of so-called chance. We can but take the individual with his eons of race history behind him and his few years of individual development at this time, and seek to find out where and when he went astray from the road which leads to contentment. If reductive analysis enables him to see this path again, struggle towards it, and perhaps regain it, it may be counted a success.

TREATMENT OF SYPHILIS.

THE treatment of syphilis by mercury has held sway for generations, and, on the whole, in the estimation of the majority of the medical profession, still holds the first place in treatment, although arsphenamine is still believed by some to be even more efficacious, at least in certain stages of the disease. Both mercury and arsphenamine are generally credited with the power to kill the *Spirocheta pallida*, although all authorities do not credit these drugs with such properties.

Among these is J. E. R. McDonagh, who ventilated his views in a paper read before the Hunterian Society, on April 13, 1921, and published in the *Medical Press and Circular* of December 25. He claims that mercury was used for syphilis when it first invaded Europe and was confused with scabies, leprosy, or some other skin disease. He believes that, owing largely to mercurial treatment, the type of late syphilis has changed and it is now less a bone and more a nervous disease. He says that arsphenamine also acts in the same direction, changing the character of syphilis, chiefly by increasing the amount of nervous disease. He criticises the belief that arsphenamine exerts a curative action on syphilis. He contends that neither that drug nor mercury acts directly upon the organism, but only indirectly by increasing the host's natural resistance.

Briefly, McDonagh's contention is: (1) That the chemotherapeutic agents cause the symptoms to vanish quicker but bring the cure of the disease no nearer; (2) that the word cure should never be used, as all proof is wanting in any special case that a recurrence will never appear; (3) that each case must be treated individually and for at least two years; (4) that no reliance can be placed on tests at present in vogue for regulating treatment. He believes that treatment, if judiciously administered, increases the individual's resistance, which in many cases probably alone suffices to bring about an apparent cure, though medical men should realize that they can aim only at reducing the incidence of destructive lesions to a minimum. Special stress is laid on the point that this can be brought about only by stimulating and not by destroying the resisting substance, though in the majority of cases being treated to-day, he says, the latter and not the former, is achieved.

TUBERCULOSIS AND PROSTITUTION.

IN lay circles and fiction the prostitute is often looked on as foredoomed to pulmonary consumption, largely perhaps because of the hollow cough sometimes heard in those who have become habitual street walkers. There are, of course, other possible causes of cough, such as exposure to inclement weather, the abuse of cigarettes and alcohol, etc. Doubtless there is statistical backing for the alleged frequency of tuberculosis among prostitutes, but in order to make of it a true occupational disease it would be necessary to show that it accompanied prostitution universally. Quite recently Samson (quoted in *La Presse Médicale* of December 14, 1921, xxix., 100) reports having examined 1,300 of these women in Berlin for evidences of the disease and found about 10 per cent. with active tuberculosis, about half of these being open cases. Of the 130 active cases, two-thirds were in the first stage and the balance in the second stage. The women were chiefly between the ages of 20 and 30 years and the period of prostitution was less than ten years for the oldest habituées. This 10 per cent. of cases, numerically small, is regarded as high, but no control figures for other women of the same age period are given. Among the numerous factors favoring the development of the disease are the venereal diseases, the insanitary life and natural hardships of the calling, sexual excesses, the danger of transmission from men, etc. Strange to state there was no evidence that alcohol played any serious role, for the majority of these women were temperate in that respect. Naturally, if present alcoholism would be an unfavorable causal element. There was no evidence that the syphilis which they nearly all had had exerted an unfavorable influence in precipitating the outbreak of phthisis.

TUBERCULOUS HEADACHE.

IT is now realized that there may exist a simple serous meningitis of tuberculous origin, apparently an abortive form of basilar meningitis which sets up adhesions and obstructs the exit of the liquor from the cranial cavity. This affection is manifested by a headache of a neurasthenic or migrainous type. The patient usually presents a benign form of pulmonary tuberculosis. There is increased endocranial tension which, according to Frisch and Schuler (*Wiener klinische Wochenschrift*, December 15, 1921, xxxiv., 50), may be recognized by the *x*-ray. Lumbar punctates may be normal or may exhibit high pressure, pleocytosis, and increased albumin. In this case the process is acute and the *x*-ray negative, while in that of negative punctate and positive *x*-ray the condition may be regarded as chronic. In addition to direct attack by bacilli and the consequences of adhesion formation, the tubercle toxins are accused in connection

with this type of meningitis. While bacilli have not yet been discovered in punctates the latter fluid has produced positive inoculation. In regard to the positive *x*-ray finds these apparently consist of accentuated *impressiones digitatae* on the inner aspect of the skull, as indicative of increased endocranial tension due to the acquired hydrocephalus internus. Since the same find has been noted in typical migraine the latter may be suspected of having a paratuberculous nature. Serous tuberculous meningitis manifested as headache may be placed in part under tuberculous absorption lesions, such as are seen in various other organs.

News of the Week.

Influenza Deaths in London Increase.—The mortality figures made public on January 20 show no abatement in the outbreak of influenza in the United Kingdom. During the week ending on that date there were 1262 deaths from the disease, an increase of 443 over the previous week, besides 707 deaths from bronchial pneumonia. The aged are particularly affected, the deaths in London, for instance, including 116 persons whose ages ranged between 65 and 75 years. Greater London is still the storm center of the outbreak, 1021 Londoners having succumbed out of a total of 1262.

Plague in Queensland.—With the advance of the Australian summer bubonic plague is reported to be slowly increasing. The Australian *Medical Journal* says that infected rats are to-day spread over 1000 miles of Queensland coast and it warns the people of Australia that "they are entering a period of dire peril."

A New Drug Bill.—Charles D. Donohue of the New York Assembly introduced a new drug bill in that house on Jan. 24. The bill is like the old Whitney law except that no department of narcotic control is provided for. The unauthorized possession, sale, distribution, or administering, dispensing, or prescribing, of cocaine, opium or any of their derivatives, or Indian hemp is forbidden. The drug trade is authorized to deal in drugs along the lines provided by the Harrison Federal law, and physicians are permitted (*permitted!*) to prescribe or dispense narcotic drugs under certain restrictions. Hospitals are authorized to treat addicts, and provision is made for committing patients to hospitals for such treatment. Physicians prescribing drugs must write prescriptions in duplicate, and the apothecary is required to file one of the prescriptions, in cities of the first class, with the local board of health, and in other parts of the State with the State Department of Health. The possession by a layman of a hypodermic syringe is declared unlawful.

Conference of Heads of Government Hospitals.—A five days' conference of the heads of 107 Government hospitals caring for ex-service men held its opening meeting on January 17. Brigadier-General C. E. Sawyer of the Medical Reserve Corps, physician to President Harding, made the opening address in which he stated that President Harding was satisfied with the Government's efforts for the relief of disabled veterans. He believed that cases of injustice that had been reported were individual, and did not reflect upon the general plan for Government relief. To-day there are being hospitalized under Government control, in Federal hospitals, 22,440 World War veterans, who are distributed among the various departments as follows: United States Public Health Service, 16,373; army hospitals, 1681; navy hospitals, 1059; soldiers' homes, 2500; Department of Interior hospitals, 827. This does not take into account patients in contract hospitals, who now number 9066. This enumeration demonstrates something of the scope and nature of the work for which the members of the Board of Hospitalization are responsible. There are now under construction 7592 beds which will be ready for occupancy within the next few months, and that the Government is at present contemplating at least 2500 more beds under the new Langley bill. So ultimately the Government will have under its direct administration hospital capacity for a minimum of 32,000 patients, which is estimated to be the peak of the load."

Immunization Against Diphtheria Among New York School Children.—Dr. William H. Park, director of the Bureau of Laboratories of the New York City Health Department, recently made the statement that with the aid of the American Red Cross, 145,000 children had received preventive treatment against diphtheria. Coincident with this effort to confer immunity against diphtheria it is shown that there has been a decrease in the number of cases of diphtheria and in deaths from the disease. From the latter half of 1920 to the latter half of 1921 the number of cases has been reduced by 1852 and the number of deaths by 155. The cost of 10,722 cases of diphtheria in the first six months of 1921 and of 611 funerals was, at the minimum figure, $581,825. The cost of immunizing a child against diptheria is 25 cents and 1,000,000 school children could receive this protection at a cost of $250,000.

Governor Miller Resents Passage of Sheppard-Towner Bill.—In an address delivered before the annual convention of the New York State Bar Association Governor Miller protested against Federal meddling with purely State affairs, and especially resented the passage of the Sheppard-Towner bill. He said he had no quarrel with the object sought by this law, but the work could be done properly only by local agencies. Furthermore, he declared the law to be unconstitutional. "A discovery seems to have been made by Congress of a new and hitherto undreamed of power to legislate on any subject which it deems to involve the general welfare." But he pointed out that the Constitution itself precisely defines the things Congress may do "to provide for the common defense and general welfare. And none of these specifically defined and enumerated powers includes the practice of medicine or midwifery." With the Sheppard-Towner law as a precedent, the health department of every State may be brought under the supervision of a Federal department of health. A child welfare bill embodying Governor Miller's views, will be introduced into the Legislature this week.

Government Monopoly of Liquor Sales Proposed.—A reorganization plan for the control of liquor traffic is being drafted under President Harding. The New bill proposes the creation of a Government monopoly on the sale of liquor for medicinal purposes, through the Public Health Service, taking

the entire trade of whiskey out of private hands and placing it exclusively in the hands of Federal officials. All liquor prescribed for medicinal uses would be dispensed directly by local offices of the Public Health Service, and all excise taxes on liquor would be removed and the Government's revenue come through profit on the sale of the liquor.

Hospital Notes.—Ground has been broken for the foundations of four additional units of the County Hospital at Sacramento, Cal. The aggregate cost of the new buildings will reach $364,030.

Plans have been approved for the erection of a hospital in Chippewa County, Mich., as a memorial to the veterans of the Civil War, the Spanish-American War and the Great War. The hospital is to cost not less than $100,000 and is to be financed by a Chippewa County bond issue.

A large addition to St. Joseph's Hospital, South Bend, Ind., is to be erected soon. A part of the new building is to be equipped as a maternity hospital. Dr. J. B. Perteling has been elected president of the hospital staff for the coming year.

A new West Side General Hospital, costing about $250,000 and containing 100 beds, is to be erected at 225 Prescott Avenue, St. Paul, Minn., the site of the present hospital.

The Board of Directors of the City Hospital, Lincoln, Neb., have made arrangements looking to the completion of a new city hospital during the present year.

The City Isolation Hospital of New Britain, Conn., has been reopened to provide accommodations for needy sufferers from tuberculosis.

Colonel Charles Lynch, M. C., editor-in-chief of "The Medical Department of the United States Army in the World War," sailed on the United States Army Transport *Cantigny* on January 19, for a three months' tour abroad, with the object of making special observations with regard to the medical and surgical histories of the World War now being compiled by the medical departments of Great Britain, France, Italy, and Belgium.

Dr. Otto Glogau of New York City has been elected an Honorary Member of the Vienna Otological Society.

Dr. Hubert Work of Colorado, President of the American Medical Association, and First Assistant Postmaster-General, will succeed Will H. Hays as Postmaster-General, according to a report from Washington.

Dr. William H. Hobbs has been appointed chief of staff of the Binghamton (N. Y.) Hospital, to succeed Dr. F. M. Miller who has been made consulting surgeon.

Dr. David L. Edsall of Boston has been appointed dean of the school of public health to be created at Harvard University with a $2,000,000 gift from the Rockefeller Foundation. This fund is to be named in honor of Dr. Henry Pickering Walcott, '58, senior member of the Harvard Corporation. Dr. Walcott was a pioneer in public health and a leader in its advocacy for forty years.

Charitable Gifts and Bequests.—An anonymous gift of $100,000 has been given to Yale University for the establishment of a professorship in honor of Dr. William H. Carmalt, who retired a few years ago after half a century of distinguished service in surgery.

Bequests of $5,000 each are made to the Lenox Hill Hospital, New York, and to the New York Association for the Blind, by the will of Ida Barh Iden.

The Memorial Hospital, Orange, N. J., is the recipient of a bequest of $2,000 under the terms of the will of Mrs. Calista S. Mayhew.

Harvey Society Lecture.—Mr. Joseph Barcroft, F. R. S., Fellow Kings College, Cambridge, will deliver the sixth Harvey Society Lecture at the New York Academy of Medicine, Saturday evening, February 11, at eight-thirty. His subject will be "The Raison d'Etre of the Red Corpuscle."

The Middleton Goldsmith Lecture of the New York Pathological Society will be delivered at the New York Academy of Medicine, Friday evening, February 3, at 8.30 o'clock, by Professor Thomas Hunt Morgan of Columbia University. His subject will be "Some Possible Bearing of Genetics on Pathology."

The Rockefeller Institute for Medical Research on January 20 celebrated the 20th Anniversary of its foundation with a reception at which brief speeches were made by Mr. John D. Rockefeller, Jr., of the Board of Trustees and Dr. William H. Welch of the Board of Scientific Directors.

St. Mark's Hospital Reorganizes Urological Department.—The Urological Department of St. Mark's Hospital has been reorganized under the control of Dr. Victor C. Pedersen, with daily service in two division on alternate days. An opportunity is afforded for young men to receive instruction as assistants in the clinic. Application should be made to Dr. Pedersen.

Medical Society Elections.—The Telfair Medical Association, at its meeting held in Helena, Ga., December 21, 1921, elected the following officers for the ensuing year: *President*, Dr. W. H. Born, McRae; *Vice-President*, Dr. F. R. Mann, Lumber City; *Secretary and Treasurer*, Dr. G. J. Maloy, Helena.

The Eastern Panhandle Medical Society, at its annual meeting held in Martinsburg, W. Va., December 17, 1921, elected the following officers for the ensuing year: *President*, Dr. G. J. E. Sponseller, Martinsburg; *Vice-President*, Dr. D. P. Fry, Hedgesville; *Secretary-Treasurer*, Dr. G. P. Morrison, Martinsburg.

The Hartford Medical Society, at its annual meeting held January 2, 1922, elected the following officers for the ensuing year: *President*, Dr. George N. Bell; *Vice-President*, John B. Boucher; *Secretary*, H. Gildersleeve Jarvis; *Assistant Secretary*, Arthur B. Landry; *Treasurer*, Philip D. Bunce; *Librarian*, Walter R. Steiner; *Trustees for three years*, Dr. E. K. Root, Dr. Frederick S. Crossfield, Dr. William Porter.

The Belmont County Medical Society, at its annual meeting held in Wheeling, W. Va., December 20, 1921, elected the following officers for the ensuing year: *President*, Dr. F. S. Wright, Bellaire; *Vice-President*, Dr. F. R. Dew, Barnesville; *Secretary-Treasurer*, Dr. J. S. McClelland, Bellaire.

The Camden City (N. J.) Medical Society, at its annual meeting held January 3, 1922, elected the following officers for the ensuing year: *President*, Dr. J. Lynn Mahaffey; *Vice-President*, Dr. O. W. Saunders; *Secretary*, Dr. E. S. Hummell; *Treasurer*, Dr. W. H. Pratt.

The Marion County Medical Society, at its annual meeting held in Marion, Ohio, January 3, 1922, elected the following officers for the ensuing year: *President*, Dr. C. M. Lewis; *Vice-President*, Dr. C. M. Crane; *Secretary-Treasurer*, Dr. Dana O. Weeks.

Obituary Notes.—Dr. Henry Ferdinand Riedel, a retired physician of Brooklyn, N. Y., died of pneumonia on Jan. 17, at the age of eighty-two years. He was graduated from the Erlanger University, Bavaria, in 1859 and was a surgeon in the Bavarian Army. He was at one time resident physician of the Lenox Hill Hospital, later superintendent of the Emigrant Insane Asylum on Ward's Island, and more recently consulting surgeon to St. Catherine's Hospital, Brooklyn.

Dr. Edwin E. Campbell of Alexandria Bay, N. Y., a graduate of the Chicago Homeopathic Medical College in 1885, died on January 3, at the age of sixty-five years.

Dr. Fanny Wohlfeil Apfel, retired, of Brooklyn, N. Y., died on January 5, at the age of eighty-one years. She was graduated from Lemberg University, Austria, and was in the Austrian governmental service during the cholera epidemic in that country in 1853.

Dr. Joseph Birbeck Burroughs, physician, explorer, and author, died in Chautauqua, N. Y., on December 26, at the age of sixty-seven years. He was graduated from Syracuse University Medical School.

Dr. Walter Watson, a retired physician of Mount Vernon, Ill., died in a hospital in St. Louis, Mo., on January 8, at the age of seventy-one years. In 1904 he was chairman of the State Democratic Central Committee and for a time was superintendent of the State Hospital for the Insane at Jacksonvile.

Dr. John Christopher O'Connor, a graduate of Bowdoin Medical College in 1905, died at his home in Manchester, N. H., on January 8, at the age of forty-three years. He was a member of the American Medical Association and of the Medical Reserve Corps of the Army.

Dr. Edwin G. Booth, one of the few surviving officers of the Confederate States Navy, died at his home in Williamsburg, Va., on January 5, at the age of eighty-three years. He was taken prisoner, together with Admiral Buchanan and others, in the battle of Mobile Bay. Dr. Booth was graduated from the University of Pennsylvania School of Medicine in 1861.

Dr. William Phillips Carr, formerly of Washington, D. C., died at Summit Point, W. Va., on December 28, at the age of sixty-four years. He was graduated from George Washington University School of Medicine in 1888, and was clinical professor of surgery in that institution. He was a Fellow of the American College of Surgeons and of the American Medical Association, a member of the Southern Surgical and Gynecological Association, Medical Society of the District of Columbia, Washington Academy of Sciences, Association of American Anatomists, and Washington Gynecological Society. He was consulting surgeon at Washington Asylum Hospital and at the Government Hospital for the Insane at Anacostia.

Dr. Harry Walter of Spring Mount, Pa., died at Sarasota, Fla., on December 18, at the age of sixty years. He was graduated from the University of Pennsylvania School of Medicine in 1892.

Dr. Louis P. Hinn of Fond du Lac, Wis., a graduate of Hahnemann Medical College and Hospital, Chicago, in 1885, died on December 31, at the age of sixty-five years.

Dr. J. W. Arnold of Columbus, Ind., died suddenly on December 26, at the age of sixty-nine years. He was graduated from the Central College of Physicians and Surgeons, Indianapolis, in 1885.

Dr. Roland DuJardin of New York, a graduate of the New York Homeopathic Medical College in 1894, died on January 8, at the age of sixty-six years.

Dr. Edward V. Kennedy of Brooklyn, N. Y., died in a Newburgh hospital following an operation for appendicitis, on January 10, at the age of thirty years. He was graduated from the Long Island College Hospital, Brooklyn.

Dr. Kingman Porter Moore of Macon, Ga., died suddenly in Pompano, Fla., on Jan. 15, at the age of seventy-eight years. He was a graduate of the Baltimore Medical College in 1868. He was a member of the American Medical Association, served as secretary, vice-president and president of the Georgia Medical Socoety, and was an honorary member of the American College of Surgeons.

Dr. Bailey P. Lester, a graduate of Vanderbilt University Medical Department in 1879 and of the University of Nashville Medical Department in 1882, died at his home in Woodbury, Tenn., on Jan. 5, at the age of sixty-four years.

Dr. J. H. Warren Meyer, Lieut. M. C., U. S. Marines, died of pneumonia in Denver, Col., on Dec. 17, 1921, at the age of thirty-eight years. He was graduated from Rush Medical College, Chicago, in 1907.

Dr. John Cassell Rogers of Kansas City, Mo., a graduate of New York University Medical College in 1875, died of heart disease on Jan. 9, at the age of seventy-eight years. He was a member of the American Medical Association and of the Jackson County Medical Society.

Dr. John Kurrus of New York, a graduate of the College of Physicians and Surgeons in 1899, formerly on the staff of the Harlem Eye and Ear Hospital, died suddenly of heart disease on Jan. 17, at the age of fifty-six years.

Service Bureau.

Regular subscribers to the Medical Record who desire information on any professional matter are invited to send their inquiries to the office of publication. Replies will be sent by mail as promptly as possible. Questions and answers of general interest may be published from time to time. When abstracts of articles from other journals are furnished the cost of typewriting will be charged.

Purchases will be made of articles of any description wanted by subscribers; a check sufficient to cover the cost should be sent with the order.

Subscribers visiting New York are welcome to use the office, 51 Fifth Avenue, as a temporary address for receiving and forwarding mail, telegrams, or small packages.

Correspondence.

LETTER FROM SWITZERLAND.

(From Our Own Correspondent.)

GENEVA, January 1, 1922.

Molière's Centenary.—The Academy of Medicine of Paris has done a graceful act in deciding to keep the tercentenary of that sworn enemy of charlatans—Molière. As Dr. Cabanès wittily remarked: "It is precisely because Molière handled Diafoirus and his confrères so roughly that we owe him a tribute of gratitude. By inveighing against purging, blistering, and blood-letting he provoked the recrudescence of arteriosclerosis, uremia, and gout, and paved the way of the medical fraternity of to-day to fortune. Let us not be ungrateful." The French Chamber of Deputies, which has always contained a fair number of doctors—M. Clemenceau among them—is clearly of the same opinion, for it has voted 200,000 francs to meet the expenses of the celebration.

Radium Therapy.—At a recent meeting of the Medical Society of Geneva the question of radium therapy was very thoroughly discussed by Drs. Wassmer, Besse, Kotzareff, Du Bois, Julliard, and others, and the work done by Besse on the biological action of radium is particularly instructive. The activity of radium may be regarded as a stimulant of cellular life, but in actual practice it is used as an agent of death. When the rays are normally applied they do not kill all the cells but make a selection (electivity); when they are filtered this electivity may persist, but to a lesser degree; with a strong dose uniform destruction (indifference) ensues. The action is not immediate, a certain latent phase elapses. The elements attacked are sometimes of the highest biological order, but usually are indifferent elements. The action of the Roentgen rays is practically *nil* on bacteria, that of radium is moderate. In *vitro* Koch's bacillus shows phenomena of excitation and of development when the dose of the radium rays is small. In the patient it is possible that there is both excitation of the bacillus and organic defence and with larger doses destruction of the tuberculous tissues. The action of radium on the gonococcus is particularly useful as it kills this organism and modifies the lesions produced by it. Moderate doses of radium rays have an inhibitory and destructive effect upon plants, producing monsters. On the other hand, weak doses increase the plant production about 40 per cent.

On the higher animals and man the action of radium varies according to the tissue and cells. The hematopoietic organs are very sensitive to the action of radium. In the spleen destruction of the lymphocytes and disappearance of the follicles take place. According to the dose and length of the exposure there is increase or diminution of the leucocytes, hemolysis, loss of opsonising power, etc. In the bone marrow only weak excitation will produce proliferation. A thickening of the vessel walls and endothelium is observed. The spermatozoid is destroyed in the testicle and atrophy of the Graafian follicles in the ovary ensues. The action of radium on the thymus is the same as that of the Roentgen rays, resulting in atrophy of the gland. The action on the thyroid is slower; in young goiters and in Basedow's disease splendid results have been obtained. According to the dose employed radium produces degeneration of the muscles, excites cartilage, while the nerve cells and elastic fibers are very resistant. The process of curative action may be tabulated somewhat as follows: (a) destructive in carcinoma, (b) corrective in sarcoma, (c) causing hyperplasia in angioma, (d) reactivating in cheloid.

Diseases of metabolism have been treated by radium, especially in Germany. In acute articular rheumatism it is useless, but some results have been obtained in gonorrheal rheumatism of the mixed variety. In arthritis deformans about 50 per cent. of improvement may result if the subject is young and the affection recent. In gout the action of radium, like that of radioactive waters, is at first painful but after a time the pain subsides and the tophi decrease in size. There is an action on the body fluids made evident by superproduction of the ferments and also, perhaps, a dissolving physical action on the tophi. In diabetes there is an excitation of the leucocytic and glycolytic ferments. In uremigenous nephritis radium possesses a diuretic, laxative, tonic, and above all a urico and ureosecretory action which should be more frequently availed of in practice.

International Diploma in Hygiene.—This semester has seen the first course for an International Diploma in Hygiene, the universities of Cambridge, Paris, and Zurich being the first to offer this degree. The course of lectures designed by the University of Paris is much shorter than at Cambridge, being intended to meet a national as well as an international need. Not only French medical graduates but also foreign physicians who hold either the M.D. of Paris or a foreign degree recognized by the University are admitted to the course. The University of Zurich also admits foreign physicians to this course. The University of Cambridge requires that all candidates for this diploma shall have matriculated and resided in the University for not less than two terms or for one term and during the long vacation course.

1. The Challenge of the Chronic Patient to the Medical Profession.—Joel E. Goldthwait arraigns the medical profession for its lack of interest in chronic medicine, as demonstrated by the present-day organization of our hospitals and by our textbooks of medicine and surgery as they exist to-day. A point which we should seriously consider is that with the patients having chronic disease who are now accepted for study, un-

less something is done with the elaborate examinations which are being made, other than to report negative findings, not only is the patient harmed by the common hopeless or indifferent prognosis given, but the profession is rendering itself liable to ridicule. In the study of many such records the writer has been surprised at the lack of consideration given to anatomical structure or the general appearance of the patient. Not only do individuals vary in structure—muscles, bones, viscera, and potentials of activity—but with considerable regularity such structure carries with it its own potential of disease. For instance, with the stomach and intestine, the many malpositions, with the possibilities of the maladjustment leading to disturbance of the physiology, should be too evident to require mention, but the fact that such physiological disturbances are capable of correction by mechanical means other than operation does not seem to be fully realized. As illustrative of a good deal of general reasoning is the attitude held to-day regarding the chronic arthritic and focal infection. That the recovery from joint symptoms which follows the removal of teeth or tonsils is at times due to this specific treatment there can be no question, but that all cases which ultimately recover do so because of this, anyone who has seen much of such cases must question. Most of these cases are due, so far as we can see to-day, to complex disturbances of the physiology as it concerns the abdominal structures, in which probably no one organ is wholly at fault. Imperfect drainage of the bowel may be a factor, but the imperfect drainage of the ducts of other viscera may be as important, or the character of the secretion of the different glands or organs may be changed by disturbances of the blood supply. The problem of the chronic arthritic, if studied with reference to the physiological potentials of the special individual, should be most hopefully faced. Make the most thorough examination of the patient that is possible, but first study the anatomical structure of the individual with the special physiology that is peculiar to such special structure, as well as the disturbances of physiology that should be expected, as the body is used by the special case, and some of the special tests will take on new significance, so that the cases become understandable and relief can be offered.

4. Common Pulmonary Diseases Confused with Tuberculosis.—Edward O. Otis asserts that a mistaken diagnosis of tuberculosis is not at all uncommon. Among the frequent errors of mistaken diagnosis are chronic affections of the upper respiratory tract, such as nasal obstruction, causing chronic cough and symptoms of bronchitis, and diseases of the nasal sinuses, the tonsils or a chronic pharyngitis. The differentiation from tuberculosis in these cases depends upon the fact that there is, as a rule, no constitutional disturbance indicating a general infection, such as rapid pulse, increased temperature, etc. To avoid the error of mis- a history of influenza, the sputum should be examined the upper respiratory tract in doubtful cases. When there is suspicion of tuberculosis in a patient giving a history of influenza, the suptum should be examined frequently and the patient kept under close observation. Likewise the sputum should be examined in all cases of chronic bronchitis. There is a condition not infrequently met with, perhaps more frequently in children, which is designated by some as a chronic pneumonia, by others as subacute or chronic bronchopneumonia. Tubercle bacilli are never found in these cases. There is involvement of a part or the whole of a lobe, indicated by dullness, impaired or modified respiration, and an abundance of moist râles. The significant fact is that this infiltration is practically always confined to the lower lobe. The *x*-ray, which one would expect to show marked evidence of disease, shows nothing at all, or some intensification of normal bronchial shadows. The differential diagnosis from tuberculosis in this class of cases depends upon the absence of the tubercle bacillus, the location of the lesion always at the base, and the absence of marked constitutional symptoms. Furthermore, the rapid recovery is opposed to a tuberculous lesion. Such cases are perhaps described as tuberculosis more often than any other pulmonary lesion, and are not infrequently sent to a sanatorium. The differential diagnosis of bronchiectasis is made from the kind of cough which is paroxysmal, the absence of tubercle bacilli after repeated examinations, and the frequent appearance of good health even after the disease has existed for a long time. The lesion is generally situated in the middle or lower lober, and the fingers are frequently markedly clubbed. It is not justifiable to make a diagnosis of tuberculosis because a man has been a stone cutter or exposed for years to other kinds of irritating dust. In returned soldiers with a history of having been gassed, the writer has not been able to discover evidence of tuberculosis. That gas inhalation conduces to the development of tuberculosis has not, he believes, in the experience of most observers, been demonstrated. It is unjust and often cruel to the patient to make a definite diagnosis of pulmonary tuberculosis without good and sufficient evidence.

3. The Treatment of Early Infantile Paralysis as Based on the Physiological Indications.—Henry O. Feiss takes issue with the plan of the Harvard Infantile Paralysis Commission, which recommends that the treatment of infantile paralysis in the early period should be rest and fixation. On the ground that (1) the muscles are still reasonably good at the beginning; (2) that as a result of the diminution of pressure in and about the spinal cord a certain amount of improvement tends to take place spontaneously, and (3) this improvement takes place early, Feiss claims that it is physiological to apply function as consistent with the normal conditions of life as possible. This means not massage and electricity, which are only local in their effects, but the striving to obtain function through physiological agencies. Broadly speaking there are three kinds of motor function in striated muscles: (1) That willed by effort, (2) subconscious, and (3) reflex. In early infantile paralysis it is necessary to make trial of all three kinds. The writer has applied this principle in about twenty cases of early infantile paralysis in a local mild epidemic in Cleveland, with very encouraging and in some instances even startling results, especially when treatment was instituted early and strenuously.

4. Optic Neuritis in Serum Sickness.—V. R. Mason reports the case of a patient admitted to the hospital on the second day after the onset of acute lobar pneumonia. Type I pneumonia were grown from washed sputum and the patient received 500 c.c. of Type I antipneumococcus serum intravenously. His temperature fell by crisis on the seventh day of the disease. Severe serum sickness appeared on the ninth day, and was present for fourteen days. During the course of the serum sickness a well-marked, bilateral optic neuritis was observed associated with marked lethargy and an increase of the globulin and cellular content of the cerebrospinal fluid. The fundi of two other patients

with serum disease were also examined, one of whom was suffering with cerebrospinal meningitis and the other with Type I pneumonia. Both of these showed temporary bilateral optic neuritis and similar changes in the cerebrospinal fluid. These three cases are believed by the writer to represent reactions on the part of the nervous system to the parenteral introduction of foreign protein into a susceptible individual. Since in each instance the urine was normal or contained only a slight trace of albumin and since optic neuritis following acute lobar pneumonia is rare, and in the recorded instances in which it has occurred permanent visual changes have resulted, it would seem that the introduction of the foreign protein into these sensitive individuals was responsible for the eye condition. It is possible, furthermore, that in some cases optic neuritis might be the only symptoms of hypersusceptibility to a food or other protein.

5. Medicolegal Application of Blood Group.—J. Arthur Buchanan refutes the statement that the blood group offers criteria of value as a means for identification in certain instances and for the fixation of responsibility of parentage in others. He has reviewed family pedigrees covering three generations which show very distinctly that the group in the children is limited only by groups represented in their ancestors. Blood groups occur in either a homozygous or a heterozygous state; if the former the children are all of the same group as the parents, and if the latter, the groups present in the grandparents will appear. It is possible that a certain blood group may appear as the dormant character and this would offer a possibility for the miscarriage of justice if the blood group were utilized as a criterion of parentage. The only instance in which it appears that the blood group could be held as direct evidence would be in a family of four or more children in whom one was of a different group than the evident group represented in both parents and all four grandparents. Buchanan hopes that no court of justice will ever utilize a means of adjusting a dispute that is surrounded with such possibilities of leading to the miscarriage of justice.

6. Intravenous Injections of Glucose in Toxemia of Pregnancy.—Paul Titus and M. H. Givens, finding that the intravenous injection of glucose for pernicious vomiting of pregnancy gave fairly uniform and successful results, have applied the same treatment to other toxemias of pregnancy, eclampsia in particular. The usefulness of glucose and other carbohydrates seems to be based on the fact that in toxemia of pregnancy there is a carbohydrate deficiency in the maternal organism, due to an unusual demand for carbohydrates on the part of the fetus. This deficiency may be augmented by deficient or improperly balanced diet. The reserve store of glycogen in the liver is drawn upon, and the organ thus depleted of glycogen. Pathological changes in the cells result, and its detoxicating and other normal functions are promptly impaired thereby. Disturbances in the kidney function so commonly seen in the various toxemias of pregnancy are probably secondary to the hepatic changes. Successful results have been obtained by the use of carbohydrates among 68 patients now reported, in addition to the series of 76 previously reported. Immediate clinical improvement in individual patients, as well as a general lowering of the mortality rate in eclampsia, has been noted in the clinic of the Western Pennsylvania Hospital as the result of the intravenous administration of glucose for this condition. Chorea gravidarum, preeclamptic toxemia, and fulminating toxemia with ablatio placenta have likewise shown favorable results from this treatment. The usual necropsy findings in the liver of patients dying from any toxemia of pregnancy were found to be distinctly altered if the patient was given an intravenous injection of glucose solution before death. Those portions of the liver lobules which were ordinarily necrotic were thereby restored to a marked degree. The usual injection consists in 50 to 75 gm. of chemically pure glucose dissolved in from 250 to 500 c.c. of water. Single doses repeated as required are preferable to a continuous flow of the solution into the vein. It is thought that the rate of absorption and storage of the injected sugar is an index to the condition of the liver. Glycemic curves plotted from blood sugar determinations at stated intervals after injection of glucose disclose the fact that the sugar is absorbed and stored by some patients more rapidly than in normal controls, whereas in others the storage is slower than normal. A prognosis based on the first curve, therefore, is favorable, because this liver may be assumed to be depleted of glycogen but able to restore itself when given an opportunity, whereas the slower rate indicates liver necrosis with loss of function.

8. The Clinical Application of the Audion Amplifier.—Magnus J. Myres explains the theory of the vacuum (amplifying) tube and describes the recording apparatus, which make it possible to obtain a graphic record of sound. This device magnifies the electric waves of a telephone circuit and is the beginning of a "microscope" for the ear. The amplifying tube means enlarging the field of diagnosis. It has been shown that the heart sounds occupy a longer period of the cardiac cycle than generally has been known. This probably is due to vibration beyond the range of the average ear. A third sound, presystolic or diastolic, in time appears in all records of normal hearts examined. Its significance has not yet been determined. Joint and muscular movements give rise to vibration; this field is new and open to investigation. By means of a variable damper, the period of heart and lung sounds can be ascertained. This, in questionable cases, will aid in accurate differential diagnosis. Experiments with the cardiac amplifier and recorder are being conducted in the U. S. Signal Corps Research Laboratories, and the writer hopes to be able to show sufficient records of normal and pathological heart and lung sounds to establish the permanent worth of this system.

7. Plague on Board Ship. W. W. Clemesha.

1. The Relationship of Uremia and Hyperpiesia.—H. Batty Shaw asserts that uremia is a complete misnomer based upon the erroneous opinion that the urine or renal excreta by retention from kidney diseases cause uremia. Probably all cases of socalled primary disease of the kidney may owe all signs and symptoms and the actual diseased condition of the kidneys to altered conditions of the blood, from some infection whether chronic or not, *e.g.* syphilitic toxemia and various bacterial toxemias. In hyperpiesia we can find all the manifestations familiar to use in the past as uremic. Some of Bright's contemporaries firmly believed that albuminuria and dropsy, and presumably other symptoms and changes associated with them, even the kidney disease, were due to some general cause operating in the circulatory system. The relationship between uremia and hyperpiesia is easily settled. Since hyperpiesia reveals in its advanced stage each and every manifestation met with in uremia, when a case presents socalled uremic manifestations, hyperpiesia is present, and if it is absent, then at death cardiac hypertrophy will be found, showing that it has been present at one time or another. "Hypersiesia" and "hyperpiesic" are words preferable to "uremia" and "uremic;" they do not commit one to an exclusive pathology and are infinitely more accurately descriptive. The writer regrets that he cannot describe the poisons circulating in the blood which produce hyperpiesis or any of the other symptoms of hyperpiesia, but he feels sure they are in the blood, and that they are in no way expressive of defective action of the kidneys. He thinks that many of the phenomena met with in the later stages of hyperpiesia, when symptoms of a so-called uremic character develop, are much more likely to be due to toxins present in the blood, as the result of some inflammation, somewhere in the body, than to metabolites present in the blood in excess owing to de-

fault of the kidney whose duty it is to extrude such bodies.

2. Serological and Morphological Characteristics of the Pneumococcus.—A. L. Urquhart presents an analysis of organisms isolated from 77 cases of pneumococcal infection and has correlated the results with those of the Rockefeller and other workers by means of Rockefeller anti-pneumococcal serums, so that it was possible to compare the results obtained with those of Lister and American workers. From this work he draws the following conclusions: (1) That from the laboratory methods employed the pneumococcus presents its most typical appearance in fresh body exudates, and that bile solubility and the absence of hemolytic activity are almost constant characteristics of the pneumococcus. (2) That for the separation of pneumococci in sputum and pus, Dudgeon's method is a convenient and satisfactory one. (3) That the fermentation reactions of the pneumococcus are of no value for the division of the organisms into types. (4) That pneumococcal antibodies corresponding to the type of pneumococcus responsible for the infection, though not present in the early stages of the disease are usually formed in the postcritical blood serum of cases of lobar pneumonia, and in the later stages of some other pneumococcal infections. (5) that the pneumococci responsible for lobar pneumonia and other serious pneumococcal infections in this country are similar to those found in America and South Africa. (6) That Type IV pneumococci are capable of producing any of the serious infections due more commonly to Types I and II infections.

3. The Importance of Thoracic Respiration.—W. Arbuthnot Lane calls attention to the importance of the part played by thoracic respiration in all periods of life; to the necessity of observing its extent; to the recognition of the factors which affect it prejudicially, and considers the best mode of dealing with it and with the conditions which impair its efficiency. He points out that in observing an individual passing from extreme inspiration to extreme expiration the alterations in the curve of the spinal column is a more marked feature than the elevation and depression of the costal arches. The vertebra, instead of forming a rigid rod, are freely movable in an antero-posterior plane. Curiously the physiologist makes no mention of this movement of the vertebra. The internal intercostal muscles are the most powerful extensors of the dorsal spine. Any condition that lowers the vitality of the individual, or which, in other words, reduces the capacity to expend energy, diminishes the degree of thoracic respiration. The factor that most frequently affects his is intestinal autointoxication, and this is exceedingly common, if not almost universal in civilized communities. Intestinal stasis develops at an early period in the life of the child. Sooner or later the contents of the small intestine become infected by organisms and the food-supply is contaminated. This results in a poisoning of the tissues and organs of the body, rendering them unable to perform their functions in a normal manner and reducing their capacity to resist the attacks of microorganisms. The observation of a large number of delicate children shows that in the thoracic respiration is in abeyance. The tissue in the infant in which the earliest evidence of infection by microorganisms is present is the lymphoid tissue in the nasopharynx. Later in life evidences of lowered resistance are shown in infection of the periodontal membrane, to which the name of pyorrhea has been given. Both of these conditions are secondary to stasis. A great deal of defective thoracic respiration is due to habit. Besides being very deforming it serves to diminish the oxygenation of the blood and to hasten the degenerative processes of the body.

4. The Rationale of the Wassermann Reaction.—J. E. R. McDonagh describes experimental work which shows that the protein particles in the serum in syphilis undergo three main changes: (1) There is an increase in number, most noticeable in early syphilis and which can be detected before the complement fixation test is positive. (2) Surface changes, by which protein particles lose many of their surface electrolytes, leading to changes with increase of their power of adsorption. (3) Mass changes, consisting in an increase of amino groups in early syphilis and an increase of lipoid material in late syphilis. When the electrolytes become dissipated and the protein mass has to undergo changes to compensate for the loss, the complement fixation test is positive, because the adsorptive capacity of the particles is increased with the hope of being able to take from the particles added the electrolytes necessary to restore balance. When the loss of electrolytes is just balanced by the substantive changes the complement fixation test is negative. When the electrolytes are still further destroyed, the complement fixation test is anticomplementary. Certain protein particles when rendered anticomplementary will serve as the antigen. A Wassermann reaction can actualy be undertaken with ingredients made from the patient's own blood with the sole addition of some colloidal silicic acid for use as the amboceptor. Any factor which causes the condensation of protein particles may make a normal serum, and an early and late syphilitic serum behave alike. The whole story is really that of a combat on the part of the protein particles—one of condensation versus dispersion. From this we may conclude that a negative complement fixation test does not exclude syphilis, and that a positive complement fixation test means no more than that presumably the patient has had syphilis. A degree of agglomeration and condensation occurs normally in the serum of most pregnant women. This explains why at least 10 per cent. of non-syphilitic women when they are pregnant give a positive complement fixation test, and also why repeated freezing and thawing, exposure to alterations of atmospheric pressure and to radioactive bodies, and shaking with various non-electrolytic substances, tend to make a normal serum give a positive or anticomplementary reaction.

7. A Case of Peliosis Rheumatica. H. V. Jackson.

1. The Influence of Foods Rich in Accessory Factors in Stimulating Development in Backward Children.—Harriette Chick and Elsie J. Dalyell relate the histories of nine very backward children, of ages varying from twelve to thirty-one months, in whom the addition to the diet of antiscorbutic juices and of fats containing the fat-soluble accessory factor was found to have a satisfactory result in stimulating growth and progress. The diet allotted to these children did not appear to be lacking in calories, but there was evidence that it was deficient in antiscorbutic principle and milk fat. Eight of the nine children gave a history of previous attacks of definite scurvy, and two showed bony deformities probably of scorbutic origin. It was not possible to determine to which of the accessory food factors the improvement in these children was due; probably both factors were concerned. These cases indicate that a child's capacity for recovery is considerable when conditions of privation are rectified; the normal standard was approached in six to twelve months, even after twenty-four months of retardation in growth and progress.

2. The Etiology of Rickets.—G. Bruton Sweet holds that the claim that rickets is due to a deficiency of fat-soluble vitamine in the diet has not been proved. In looking for an explanation that will satisfy all the peculiarities of rickets as shown by laboratory experiments and clinical observation, including the results of therapy, it appears to the writer that one must go further than to assign either a purely dietetic or hygienic etiology for this disease. The profound metabolic changes which occur in a severe case of this disease can, he considers, be only caused by a disturbance of those organs which control metabolism in the young. If a deficiency of endocrine secretion is the direct result

of an unsuitable artificial diet, and the latter is also the chief factor in the causation of rickets, it would perhaps not be illogical to conclude that this disease is the effect of a deficiency of the secretion produced by one or more of these organs. Of the various endocrine organs a deficiency of whose secretion is responsible for the production of rickets that of the thymus gland is most probable. A plausible reason for considering that rickets is due to thymic insufficiency is that the age incidence of the active growth of the thymus and that of the disease known as rickets is almost identical. The normal thymus does not increase in size after the age of two years, and rickets as a progressove disease is usually limited to that age. Surely these significant facts are something more than merely a coincidence. Confinement in young animals, with the attendant evils of lack of sunshine, exercise and cleanliness, are important factors in increasing the severity of the disease.

4. Blue Sclerotics and Brittle Bones with Macular Atrophy of the Skin and Zonular Cataract.—Olaf Blegvad and Holger Haxthausen, in summing up information on 156 persons having a pedigree of blue scleræ and brittle bones, find that 76—that is about one-half—had blue scleræ; and among 52 persons whose bones were examined in addition to the symptoms of the eyes, 24—also about one-half—had the tendency to fracture. They think it evident that the anomaly is inherited as a dominating quality according to Mendel's theory. In addition to the blue scleræ and fragility of the bones, other anomalies have been observed in persons of this type, such as defects of hearing, hemophilia, syndactyl and astigmatus, palatum fissum, a tendency to luxations and subluxations. A case is reported, occurring in a woman 24 years of age, in which the most interesting feature was a zonular cataract, which is a hereditary affection, and which, so far as the writer can ascertain, has not been described before in connection with Eddowes complex of symptoms. Further there is a peculiar change in the skin which, in its development and appearance, corresponds to a description given for the first time by Thibierge, who called it *athrophodermie érythémateuse en plaques à progression exentrique.* The name used in recent publications is *atrofia maculosa cutis.* Whether this rather rare cutaneous disease is found accidentally in this patient together with Eddowes complex of symptoms, or whether there really exists a connection between them it is impossible to say from a single case. If, however, one considers that the changes in the scleræ and bones are due to a defective development of the mesodermal tissue, it seems logical to conclude that the cutaneous atrophies form a part of the entire disease.

1. Some Researches of the Peri-Arterial Sympathetics.—Rene Leriche states that the systematic study of the phenomena which follow the exciting of average-sized arteries, that is, of prevailing muscular structure, reveals the existence of a very characteristic physiological reaction which never fails in normal circumstances. When the sheath of an artery is removed, just at the moment its external layer is pinched, the vessel contracts, its pulsation stops at once and its size diminishes. If you excise the cellular layer the diminution will progressively reach the third or the fourth of the normal size of the artery. This arterial contraction usually causes the pulse to disappear, but it does not altogether interrupt the circulation. The arterial contraction is the primary element of the characteristic reaction against excitation. As secondary signs in the hours following pulsation is impercentible or very feeble; the operated limb is colder than the other; there is a difference of 3° or 4° C. After three to fifteen hours following excision of the nervous layer there is an elevation of local temperature of 2° and even 3° C., central temperature not being modified, and the patient has a subjective sensation of heat. There is also an elevation of arterial pressure, which may reach 4° c.c. according to the healthy side. An increasing amplitude of oscillations is also shown by the phygmomanometer. The vasodilator reaction is transitory; after peri-arterial sympathectomy it becomes attenuated from the fifth to the sixth day and disappears after three or four weeks. At the level of the viscera absolutely nothing is known of these reactions; it is only at the level of the limbs that the phenomena resulting from an injury of the peri-arterial sympathetic plexus can be distinguished, and their analysis is not easy. One may, however, isolate two groups: In the first group the characteristic physiological reaction is pure, for instance Raynaud's symptoms are characteristic of vasomotor sympathetic disease. In the second group reaction is disturbed and gives various troubles, either as the result of contracture of too long duration or by abnormally persisting dilatation. In such cases biological disturbances are produced in the subjacent tissues, creating various associations of motor, sensitive, vasomotor, glandular, and trophic symptoms, or even signs of local necrosis. Evidence is produced to prove that modified circulation is the real cause of the various phenomena studied. This leads the writer to believe that logically the treatment of those vasomotor or trophic troubles must aim to modify peripheral circulation by peri-arterial sympathectomy. The technique is to isolate the artery on 8 to 10 cm., to fix the vascular sheath after dividing, to hold one part with a forceps and dissect off the cellular tissue either with knife or cannular sound until there has been effected complete denudation of the vessel, which becomes greatly reduced in size. This brings no injury to the arterial wall, a fact which Leriche has verified at four and eight-month intervals. He has performed this operation sixty-four times: In 11 cases of causalgia or equivalent syndromes; 2 cases of painful stumps; 19 cases of post-traumatic contractures; 4 cases of post-traumatic edema; 4 cases of ischaemic sequels; 10 cases of trophic sloughs after nerve section; 3 cases of attempt to modify tension of cerebrospinal fluid; 2 cases of Jacksonian epilepsy, and 1 case each of trophedema, of trophic slough of the heel after medullary injury, of varicose eczema, of trophic troubles after frostbite, of spasmodic paralysis, of goiter, of intermittent claudication and of erythromelalgia. In this series of cases there were remarkable successes and complete failures. The operation has been performed twice for Raynaud's disease and gave good results. The writer concludes that sympathectomy is worth trying in certain types of painful phenomena and in trophic troubles.

3. Further Data Concerning the Experimental Production of Pancreatitis.—Edward Archibald and E. C. Gibbons, from a consideration of experimental fact and clinical experience, think it justifiable to present the problem of the etiology of pancreatitis in the following way: "The conditions for actual serious damage to be done in the pancreas must pretty certainly be three: (1) A change in bile composition, increasing the bile salts; (2) undue resistance, perhaps often amounting to spasm, of the common duct sphincter; and (3) abnormal rise of pressure in the biliary system behind, either in the gall-bladder or the common duct. Animal experiments were carried out for the purpose of discovering in the facts of clinical experience circumstances fulfilling these postulates, which may be summarized as follows: (1) Infected bile, aspirated from the inflamed gall-bladder, exercises a much more necros-

ing and inflammatory effect upon the pancreas than does normal bile. (2) Chemical investigation of infected bile has not yet proved that this difference of effect is due to an increase in the concentration of bile salts as the result of bacterial action on the bile. (3) Mild grades of pancreatic swelling, as estimated clinically, are certainly possible, and are represented by edema with early necrosis of the parenchyma, presumably the result of bile invasion. The clinical statement in operation records as to the presence of a "somewhat thickened and indurated pancreas" is probably a correct interpretation of fact in most instances. (4) The gall-bladder, under conditions of irritation from stone or inflammation, is probably able to go into strong muscular contraction, and the hypothesis is set up that such contractions may cause sufficient driving force to cause invasion of the pancreas with bile. (5) The common duct sphincter is provoked to resistance not only by an acidity of the duodenal contents, but also by sudden distention of the common duct through abnormal and unexpected rises of pressure in the gall-bladder.

6. Chronic Cholecystitis without Stones: Diagnosis and Treatment.—Willy Meyer makes a plea for more careful diagnosis of chronic cholecystitis. He has sought the opinion of seven leading radiologists as to the diagnostic capabilities of radiography, from which he concludes that the assistance which the surgeons hope will be rendered by radiography in the fixation of the diagnosis of cholecystitis without stones, is in its evolution, but at present, in the hands of experts, may be relied upon as an aid in clearing up cases of recurring or permanent pain in the upper abdomen, as far as the gall-bladder carrying stones is concerned, in 30 to 50 per cent. of the cases. He says "pain in the upper abdomen" because it must be borne in mind that the subjective pain due to a diseased gall-bladder may be exceptionally confined to the left side of the upper abdomen, and may be noticed by the patient over the left costal arch and left side of the chest only. Since paying attention to this phenomenon he has noticed with increasing astonishment how frequently patients suffering with gall-stones complain of spontaneous pain in the region of the sigmoid, and not seldom also tenderness at this point. This observation has been made particularly in emergency cases sent to the hospital with the tentative diagnosis of intestinal obstruction. Inasmuch as a number of authors think the cholesterol test of the blood cannot be relied upon in the diagnosis of cholecystitis with stones, to say nothing of cholecystitis without stones, it is fortunate that the analysis of duodenal contents has stepped in and has proven one of the greatest advances clinical medicine has made in the course of the last five or six years. As a result of personal work done in this direction the author expresses the opinion that the Einhorn method of collecting the duodenal contents in a fasting condition deserves confidence, and is to be considered a reliable procedure. The Meltzer-Lyon test has little, if any, value in diagnostic respects, but it promises to be of great importance in the treatment of diseases of the biliary system. Clinically cholecystitis without stones takes the same place in the upper abdomen as chronic appendicitis does in the lower. Chronic appendicitis is generally conceded to be a surgical disease requiring operation. Chronic cholecystitis still belongs to the borderland. Though not as treacherous and deadly in its sudden attacks as the inflammation of the appendix may be, it nevertheless often undermines the patient's health, and should, therefore, as a rule require the removal of the gall-bladder. It appears that cholecystectomy is as well borne by the human system as appendectomy. The principal technical advantage, accruing from the preliminary more refined diagnosis of diseases of the bile tract in the presence of gall-bladder, combined with appendicular disease, is the indication derived from it with reference to the place of the incision. Knowing *before* operation that the bile is pathologic, one cuts down on the gall-bladder and pulls up the cecum with the appendix, instead of cutting down on the appendix and then palpating the gall-bladder region, as done heretofore. Inspection and palpation of the gall-bladder at operation must cease to render the only indication for cholecystectomy. The *quality* of the bile, determined systematically, with the help of the duodenal tube *previous* to operation, and, if desired, the condition of the bile aspirated from the gall-bladder *during* the operation, must guide the surgeon in his decision of where to incise and what to excise.

7. The Physical Treatment of Enteroptosis. Cortlandt MacMahon.
8. Anxiety. W. J. Jago.
10. General Practice and Puerperal Fever. A. Campbell Stark.

2. Empyema in Childhood.—Frederick C. Pybus bases his remarks on the first 100 consecutive cases operated on by him at the Hospital for Sick Children, Newcastle-on-Tyne. The common cause of empyema in children is the pneumococcus, this organism being present in this series in forty out of fifty-nine cases examined bacteriologically. The condition is most fatal in children under two years of age. Males are more commonly affected than females, the ratio being sixty-one of the former to thirty-nine of the latter in this series. The most important sign is dullness. Contrary to what might be expected, in most cases bronchial breathing and moist sounds can be heard over this dull area. It is this unexpected sign which accounts for so many cases of empyema being overlooked, and until this is generally realized there must be a delay in recognition and operation. In patients presenting a swinging temperature and dullness over the lung following pneumonia, the diagnosis of empyema is nearly certain. In all cases of doubt the exploring needle should be used. Aspiration for empyema is only advisable if the patient is too ill to stand incision of the chest wall, or when the condition is bilateral. Apart from this, the empyema must be opened wherever it is situated, but the majority can be opened at the optimum position, about the seventh or eighth interspace in the mid-axillary line. The author has found local anesthesia (novocaine) safer than chloroform or ether, and has the further advantage that it allows the child to be fed up to and, if necessary, during the operation, so that no starvation may result. Resection of a rib was practised in 75 per cent. of the cases in this series. More recently, in a few cases, the empyema was opened more widely, all the contents evacuated, the cavity washed out with flavine solution, and the wound almost entirely closed. While it is too early to speak dogmatically of the results, on the whole they show an improvement, and any measure which lessens the length of time necessary for drainage will be of great advantage. The mortality in the present series was 24 per cent., but many of these cases were gravely ill at the time of operation and died from general infections. The improvement of results lies in earlier recognition and operation, or the discovery of some specific remedy. The pneumococcal cases do better on the whole than those in which the streptococcus is the etiological agent.

6. The Therapeutic Uses of the Anterior Pituitary Gland.—Thomas Bodley Scott and F. W. Broderick consider conditions due to abnormal anterior pituitary secretion in two groups, those of pre-adolescence and those of post-adolescence. The former are chiefly defects of growth and development, and the latter chiefly of function. The functional failures of adult life are often the result of unrecognized developmental faults in youth. This points to the importance of careful observation in childhood. When we see children developing in a hesitating way, both in body and mind, not going straight, we are apt to think of it as a character deficiency, or we call it laziness or wilful stupidity, but it is nearly always endocrine deficiency. Anterior pituitary gland often combined with thyroid extract has been shown to be very effective in these developmental

deficiencies. This type of therapy has been effective in enuresis in both sexes, in epilepsy, and in premature senility due to endocrine deficiency. From the fact that the anterior pituitary gland governs bony growth, it seems possible that it may have some action on the calcification of the teeth. The work of one of the authors seems to point to a pluriglandular syndrome being responsible for dental caries. In a former paper the writers present evidence that after acute fevers the titration reaction of the saliva is toward a loss of alkalinity, and that this can be overcome by feeding with a plurigland containing hormones that increase the assimilation of lime salts. It is suggested that organotherapy is able to increase the calcification of teeth, both enamel and dentine, after eruption. Feeding experiments in rabbits in which plurigland was used appear to add confirmatory evidence to this suggestion.

Broncholithiasis.—Leuw states that hitherto this affection has belonged wholly to the pathologist. Clinical cases are excessively rare, and the author is evidently unable to locate a prior case report. Yet the condition itself cannot be so infrequent as appears. The patient was a laundress of 32, first seen in June, 1916. She complained of headache, a cough and a pain under the sternum. The history was negative. Physical examination brings to light nothing of importance. The patient was given Dover's powder and told to come back. She next complained of constriction of the chest, and although the *status quo* was unchanged the author was summoned later to the patient's home to avert suffocation. The patient seemed to be at the close of an asthmatic paroxysm. There was a small quantity of peculiar sputum which threw light on the case by suggesting a pneumonic focus, and the patient was carefully watched, but nothing developed. Under narcotics the distressing symptoms vanished for the time and the author adhered to his diagnosis of bronchial asthma. But several days later a similar crisis waked the patient in the night. She was found in orthopnea, but neither laryngospasm nor bronchospasm accounted for the symptoms. Patient denied having inspired a foreign body. For want of a better diagnosis the author injected morphine for asthma, but soon after, in a paroxysm of choking and retching, patient expelled a hard object which proved to be a broncholith, and the symptoms at once subsided. Since then she has been free from symptoms and the *x*-ray shows no mineral deposit in the chest.

Pathogenesis of Syphilis Maligna.—Umansky of Professor Naegeli's Dermatological Clinic at Berne, writes comprehensively on this subject. He enumerates the views which have heretofore served to explain individual cases, or which have been put forward to account for malignant syphilis as an entity. First comes mixed infection, which theory antedates our modern knowledge of symbioses. It was assumed by Tarnowsky that in malignant syphilis an unknown was added to the ordinary virus of the disease. The same view is upheld to-day in certain quarters, although no superinfection has ever been shown by bacteriological studies. Sahli is one of the more recent champions of the mixed virus hypothesis. The second view mentioned is that of resistance weakened by antecedent dyscrasia or coincident disease. It is not disputed that many factors serve as predisposition to severe course of syphilitic infection —old age, alcoholism, malaria, etc., but this cannot be the motivation because malignant syphilis attacks the young and robust. Difference in virulence on the part of the spirochetes is a very plausible view, but animal experiment seems to negative it, although the subject is far from closed. Clinically mild and malignant syphilis have been contracted from the same public women at the same time, which is sufficient to add this view to the discard. The fourth view discussed refers to a virgin character of the soil which makes necessary the belief that the entire race has at some time been tainted with syphilis and that those who have, as it were, miraculously escaped the taint contract the disease in its full form. Far-fetched as it sounds, this theory cannot be hastily passed over. Opponents who call attention to the fact that one brother contracts mild and another malignant syphilis may of course receive the reply that Mendelism could explain this anomaly. Neisser, who is the champion of the virgin soil view, candidly admits that he has seen a reinfection pursue a far more severe course than the original attack, although the reverse should be and commonly is the case. In the case of aggravated second infection, we might assume, of course, that the natural defence had been exhausted in meeting the first attack, but this would not get us any further toward a solution of the problem. The author states that the entire hypothesis of weakened defense to explain malignant syphilis involves a begging of the question, as no evidence in favor of this view has yet been adduced. Hecht, however, has sought to establish a criterion for absence of antibody formation in the failure of the lymph nodes to swell after infection and of the roseola to appear, both phenomena meaning for him that there is a production of antibodies. This does not hold good in practice, for these phenomena may not be present in certain cases of mild syphilis. Failure of a positive Wassermann is a third objective criterion cited by Hecht as often seen in syphilis maligna, but the author does not concede the value of this evidence, for there is other problematic behavior on the part of this reaction which is not readily explained, as for example, its negative behavior in certain alcoholics. The failure of the mercurial treatment in malignant syphilis is also attributed by Hecht to inability of the system to manufacture antibodies, but other antisyphilitic treatment also fails at times, and this explanation hardly suffices to cover the total lack of response to treatment. Umansky would eliminate any hypothesis which explains malignant syphilis by failure to develop antibodies and proposes a view which explains the entire disease picture in a spontaneous fashion. The latter comprises rapid course and involvement of the entire organism, absence of lymphnode reaction, refractory behavior toward treatment, etc. In other words, there is an abnormal reaction toward the syphilitic virus which has been termed by Naegeli an allergic reaction, an oversensitiveness to the virus. This behavior may be compared with other allergical phenomena. There are all degrees betwen ordinary and allergic syphilis and the malignant form is the extreme end of a series. In other words, the author makes the offending element an excess of antibody pre-existent in the tissues. When the spirochetes meet antibodies in excess the reaction is not one of the ordinary type, but a destructive lesion. In other words, spirochetes cannot be destroyed *en masse* without "breaking eggs." Malignant syphilis is not the same affection as precocious tertiary syphilis, but both have the same mechanism—the few spirochetes found in such lesions means that they have mostly been wiped out by the excessive defense put up. Destructive lesions and melting away of the tissues do not mean weak defense or no defense, many spirochetes, higher virulence, but the very opposite—a frontal attack by the organism which is costly for the latter as well as for the spirochetes. The remedies of the physician, whether mercury, or arsenic, or iodine, simply cannot get into the fight—the latter being what the Irishman called a strictly private contest in which outsiders are not allowed to participate, or like a row between man and wife. The author would drop the expression "syphilis maligna" for "allergic syphilis."

Gazette des Hôpitaux.

September 27-9, 1921, xciv, 76.

Cessation of Status Epilepticus (Jacksonian) Under Lumbar Puncture and Intravenous Injections of Distilled Water.—Leriche of Lyon refers to an earlier communication in which he agitated the possibility as mentioned above. Cases are now recorded in which the two resources separately tried by different surgeons have given a favorable result. The author was consultant in the second case. The first one occurred in the practice of Covert of Bourg. It was a military traumatic

case—a bullet in the right frontal region—in which the Jacksonian epilepsy had relapsed after an apparent operative cure. As there was hypertension of the spinal fluid Covert punctured the cord. The patient at the time was in status hemiepilepticus, and obtained a complete cessation of the convulsive phenomena. There had been no recurrence some months later and the patient is regarded as definitely cured. An intense cephalalgia with meningeal symptoms and fever was responsible for the puncture. The other case occurred in the practice of Gravier, physician to the Hotel Dieu, Lyons, in which there had been no injury, but a history of digestive troubles and migrainoid symptoms. There was a vague history of partial paralysis of the arm of short duration. While under treatment localized convulsions appeared, involving the face and arm, and eventually the entire side. Lumbar puncture showed hypotension of the spinal fluid and the author, called in consultation, tried the experiment of injecting 40 c.c. of distilled water into a vein. The crises which had become continuous ceased, although the diagnosis had been made of gumma or tumor of the brain.

Gazette des Hôpitaux.

November 15-17, 1921, xciv, 90.

Uremic Gastroenteric Ulcers.—Lemierre and Piédeliévre contribute a monographic article on this subject which was first described by Rayer in 1839, and which now has an extensive literature. Gastric ulcer of uremic origin is very rare in comparison with the enteric location. The latter are most apt to occur in the terminal portion of the ileum, but have been found from the duodenum—to which they have at times been limited—to the cecum and even to the rectum. It being conceded that they are largely autopsy finds one must ask if they ever possess clinical significance. As in the case of other ulcers they may cause severe pain and hemorrhage, under which circumstances they suggest threatened perforation. They have caused vomiting of both red and black blood, and both kinds have also escaped by the rectum; and when they occur in the colon dysentery has been closely simulated. In the clinic the patients have almost invariably been recognized as the subjects of digestive uremia, so that there has been little or no confusion with ordinary gastric or duodenal ulcer, dysentery, etc., when the patient had been properly examined. In this syndrome we find anorexia, gastric intolerance to food and especially diarrhea, with emaciation, pallor, asthenia, and some of the evidences of Bright's disease, such a retinitis, the authors also laying much stress on pericarditis. These lesions may not be recognized until a systematic examination is made. The diseases which have to be excluded, since they might be masked by the picture, are cancer of the stomach and pernicious anemia.

Le Progrès Médical.

December 3, 1921, xlix, 49.

Inguinal Lymphogranuloma.—Bory describes a condition which might be termed pseudo-chancroidal bubo, traces of which may be found in the writings of bygone clinicians. It is apt to cause much confusion in diagnosis for in addition to syphilis and chancroid it could suggest a tuberculous lesion and even bubonic plague should the latter prevail in the vicinity. While at first the bubo might appear to have originated de novo accumulation of data shows that a slight peripheric lesion may usually be found somewhere on the genitals. Aside from the diseases above mentioned the appearance of the bubo might under certain circumstances suggest Hodgkin's disease, but its unilateral location and the suppurative tendency should usually suffice to exclude this affection, as well as syphilis in pure infection. The benign character of the lesion becomes evident under continued observation and it is only at the start that confusion could arise. With this much conceded the name applied by some writers of benign subacute lymphogranuloma may answer, although this takes no cognizance of its peripheral origin. The size of the nodal enlargement is very limited—it never exceeds that of a small English walnut. Aside from a more subacute and protracted course the condition closely simulates chancroidal bubo or a suppurating tuberculous gland; for after a latent period the skin becomes reddened, the mass shows points of suppuration and the fistulæ produced after evacuation of the pus tend to persist. Suppurating gumma is at times suggested. No suppuration *en masse* and no ulceration have been reported. The fistulæ may or may not close if left untreated, but the lymphnode swelling itself does not tend to subside at all. There may be several openings and in certain cases the mass is riddled with them. There is no mention by the author of actinomycosis in this connection. The petty lesions on the genitals do not present anything characteristic and apparently may be absent in some few cases but often they resemble herpetic and even chancroidal lesions, making diagnosis difficult, although it is an easy matter to examine for spirochetes, Ducrey's bacillus or Koch's. The author describes one case with extreme detail. The début suggested chancroid with bubo and at the same time the genital sore behaved much like a herpes vesicle of abortive character, being single. Since an atypical chancre could also have been present the smears and serological tests were made with great care and inevitable negative results. The patient recalled that he had a precisely similar experience one year before which was evidently regarded as syphilitic, one seroreaction only having been faintly positive. In the present case Bory made a biopsy of the preputial lesion and later examined pus from the bubo—always with completely negative results. In addition a nodular peno-inguinal lymphangitis could be made out. Despite the absence of an exciting factor Bory was forced to conclude that the process was akin to the infectious granulomatous diseases including syphilis and tuberculosis on the one hand and some of the lymphogranulomatoses on the other. From one case on record it appears that intravenous emetine caused the disappearance of the infiltration, while the *x*-ray would doubtless be efficacious.

François Franck, Experimental Physiologist and Military Hero.—The laboratory worker often risks his life in connection with biological, chemical and other experiments and in time of war shows the same altruistic courage. The career of the late experimental physiologist, François Franck, during the Franco-Prussian war is summed up briefly in an article in *Le Progrès Médical* for December 3, 1921, xlix, 49. When the war broke out in 1870 our subject was an interne in the Saint-Andre Hospital, Bordeaux. He at once joined the squadron known as the Girondine Scouts, composed of sons of the leading families of Bordeaux. Having escaped the rout which decimated this body at Varise, he next fought in the Army of the Loire and being a fine horseman, often served as *liaison* officer, despite his medical rank. In this capacity he was struck in the thigh by a shell and captured by the Prussians. Technically a spy he was tried and condemned to death and was taken to Saarbruck where temporary fear of reprisals on the part of his captors saved him from execution. Franck always thought of escape and proposed daring attempts at prison or guard delivery which were too radical for his fellow prisoners. Once when it would have been possible for one man to escape in safety and Franck had won the lucky number in the raffle he deliberately made over his chance to the father of a family. Finally the fear of reprisal having left his captors there arrived the day before the death sentence. The moment had arrived for a desperate break for liberty and he seized upon it successfully, although he was forced to wander about disguised until the armistice. He then quietly resumed his internate.

The Devries Mutation Theory in Medicine.—Naegeli considers mutations as affecting disease exciters and observes that thus far no absolute proofs of bacterial mutation have been furnished. But mutations apparently affect human beings as seen when a slight personal deviation becomes a marked family trait. Here belong the hanging lip of the Hapsburgs and the tuft of white hair in the Dukes of Rohan. Familial diseases may be regarded in the same light, and bleeders, chlorotics and many other individuals may be looked on as mutants. —*Schweizerische medizinische Wochensehrift.*

Book Reviews.

NUT GROWING. By ROBERT T. MORRIS. Price, $2.50. New York: The Macmillan Company, 1921.

A SURPRISE awaits the reader who, from the title of this little volume, expects to find merely a treatise on the chemistry of soils and the technique of seeding, transplanting, grafting, and caring for nut trees. To be sure he will find all this, but first he will meet with a chapter entitled "General Notes," in which sociological and economic problems are discussed in their relation to the world's food supply. Dr. Morris contends that the Malthusian theory has no basis in actual facts because it has failed to take into account what he terms the "apædion" (alpha privative, paidion, child) index in relation to the cultural limitations of man and his domestic animals. In other words, Malthus and his followers have overlooked the phenomenon which the farmer knows as the "running out" of any given variety of cultivated plant or animal. He further asserts that the Malthusian theory to hold good would have to include the proposition that man is to remain stupid. He shows that with a proper appreciation of the food value of nuts and of the possibilities of their culture even in the waste places of the earth, if man is not impervious to a new idea, the grim specter of starvation need no longer dog his steps. The technical portion of the book can be understood without difficulty by the amateur agriculturist. In it the author describes with the aid of illustrations a method of paraffin grafting, in which he has made use of some of the principles learned in surgery, with the result that many difficulties heretofore encountered in tree grafting have been overcome. The method is applicable to all sorts of trees and promises to revolutionize nut growing. The sociologist and student of economics as well as the agriculturist will find the book of more than ordinary interest.

TEXT-BOOK OF EMBRYOLOGY. By FREDERICK RANDOLPH BAILEY, A.M., M.D., Formerly Adjunct Professor of Histology and Embryology, College of Physicians and Surgeons (Medical Department of Columbia University), and ADAM MARION MILLER, A.M., Professor of Anatomy, The Long Island College Hospital. Fourth Edition. With Five Hundred and Three Illustrations. Price, $6.00. New York: William Wood & Co., 1921.

THE changes in this fourth edition of this well known and popular textbook are not very extensive but, such as they are, are in the line of improvement. A number of new illustrations have been introduced to replace several which were less satisfactory. In this edition the plan has been adopted of describing the early stages of embryonic development consecutively as they occur in Amphioxus, the frog, the duck, and the mammal, instead of having separate chapters devoted to cleavage, gastrulation, and mesoderm formation, and then discussing these stages as they occur in the several forms of animal life. This is more satisfactory for it makes the none too easy subject of embryology less difficult for the beginner. A few changes, to keep pace with the new knowledge acquired in recent investigations—for even embryology is a progressive science—have been made in the later chapters on organogenesis and a chapter on fetal membranes has been added. Concerning the general plan of the work little need be said for this has been considered in review notices of the earlier edition, and it need only be added that the work of revision has made still better a book which for size, clarity of description, and excellence of illustrations was already among the highest in the list of treatises on embryology in the English language.

THE UNCONSCIOUS. The Fundamentals of Human Personality, Normal and Abnormal. By MORTON PRINCE, M.D., LL.D. Second Edition, revised. Price $3.00. New York: The Macmillan Company, 1921.

THE original edition of this now classical work appeared in 1914. In the preface to the second edition the author states that he has added four new chapters which deal respectively with the structure and dynamic elements of human personality, and the study of a special problem in personality in which these principles are involved, namely, the psychogenesis of multiple personality. Otherwise stated the lectures as originally delivered numbered twenty, but four were omitted in the first edition in order to reduce the size of the volume and these four are now restored. This increases greatly the value of the work, and is a boon to the reader because it incorporates much of the special work by Dr. Prince on Multiple Personality in the present volume.

BACTERIOLOGY FOR NURSES. By HARRY W. CAREY, A.B., M.D.; City Bacteriologist, Troy. Second Revised Edition. Philadelphia: F. A. Davis Company, 1920.

THE author was for many years lecturer on bacteriology in the Samaritan Hospital Training School for Nurses, Albany, and at the same time pathologist to the hospital. His lectures have served as a basis for the present work of 149 pages and nineteen illustrations. The total number of lectures and chapters is thirteen and they cover the practical aspect of the subject. Some of the subjects are pyogenic organisms, intestinal pathogenic organisms, immunity, sterilization and disinfection, pathogenicity of moulds and yeasts, bacteriology of water and milk, diseases due to protozoa, etc., etc. In the present edition the author endeavors to present the subject of complement fixation in a practical and simple way.

THE MAJOR SYMPTOMS OF HYSTERIA. By PIERRE JANET, Ph.D., M.D. Member of the Institute of France and Professor of Psychology in the College of France. Second Edition. New York: The Macmillan Company, 1921.

THIS work appears directly in the English language without the medium of a translation. The original edition goes back to 1907. As is known to its readers the fifteen lectures which comprise the book were delivered by the author at Harvard and the dedication is to the late Professor Putnam. The author heads the second edition with a long introduction. Since the book is one of lectures delivered in 1906 it was hardly practicable to make many radical changes. The original conception of hysteria as a neurosis, as based on observations of the disease in the Salpêtrière, with special reference to the somatic manifestations, is retained; in other words these are the "major symptoms," chiefly involving the nervous system. The psychology of hysteria, the socalled conversion, suppression, symbolism, etc., as exploited by the Viennese is not antagonized, but the older nomenclature and conception of the disease are retained. Freud is mentioned casually a few times and Stekel and other disciples not at all. Evidently controversial matter is avoided. The sex element is not mentioned at all. Every one interested in Freudian lore should read this volume in order to comprehend the possibility of a discussion of hysteria along the most conservative of lines.

LEHRBUCH DER UROLOGIE. MIT EINSCHLUSS DER MÄNNLICHEN SEXUAL-ERKRANKUNGEN. Von Prof. Dr. LEOPOLD CASPER, Universitätsprofessor in Berlin. Dritte, neu bearbeitete und vermehrte Auflage. Berlin and Vienna: Urban & Schwarzenberg, 1921.

THIS well-known textbook was originally issued in 1903 and reissued with important additions in 1910. The author departed from the usual procedure of urologists by featuring chapters on socalled medical nephritis. The delay of eleven years in publishing the third edition must doubtless be ascribed to the war. With such long intervals between editions it stands to reason that the original chapters must undergo more or less revision and rewriting to keep abreast of the times. In the third as well as second edition the author lays stress on the sections on medical nephritis and renal diagnosis. In a work of but 600 pages devoted to the entire field of urology, many subjects must be slighted and the book must be largely a record of personal experience. The American urologist can hardly understand the omission of all reference to prostatic and vesicular focal infection with especial reference to joint affections; while there are but a few lines on the entire subject of the electrical and *x*-ray treatment of urological affections, with the exception of the almost outlawed Bottini's galvanocaustic operation, which is described at length. The book is behind the times in several subjects.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS ANE GYNECOLOGY.

Stated Meeting, Held October 25, 1921.

DR. HAROLD BAILEY, IN THE CHAIR.

Sarcoma of Uterus in Infant.—Dr. STAFFORD MCLEAN reported this case. He stated that sarcoma of the uterus was extremely rare in infancy and childhood. Only twelve cases were reported in the literature. Primary sarcoma of the vagina, however, was not so unusual. The case he reported came under observation in April, 1920, and was followed for sixty-nine days, until it terminated in death. At the time of coming under observation, the baby exhibited pallor and had had a bloody discharge from the vagina for two months. The birth weight of the infant was eight pounds; she was born at full term; delivery was normal. The baby was fed on milk powder and sugar. The child was having four or five stools a day. The appearance of the infant was that of a well nourished, well developed child. The head was normal, there being no cranial tabes. The heart, lungs and abdomen were absolutely normal. There was no enlargement of the lymph nodes. There was bleeding from the vulva. The blood count showed 2,800.000 red cells and 14,800 white cells with a differential count of 40 per cent. The uterine growth involved not only the uterus but seemed to involve adjacent tissues and extended close to the rectal wall. A specimen was examined by Dr. Martha Wollstein, who reported that it was sarcoma. Three radium treatments were given at intervals of two weeks, the dose being 100 millicuries for three hours. There was no oozing after the first treatment. Six weeks from the time of admission, the mass was well down in the abdomen and about the size of an adult uterus. The child suffered from anorexia and showed extreme pallor. She failed rapidly. The autopsy findings and the pathologist's report would be published later.

Dr. HAROLD BAILEY said that one frequently heard of sarcoma of the kidney in young children, but it was extremely rare to hear of sarcoma of the uterus. A feature of particular interest brought out by Dr. McLean was that one child with sarcoma of the uterus had been cured by operation. The case reported was seen by Dr. Studdiford, Dr. Downes and the speaker, and they all felt that it was inoperable condition. Only one finger could with difficulty be introduced into the vagina. By rectal palpation a considerable mass could be felt which extended beyond the outline of the vagina and uterus. Autopsy showed an abscess cavity opening into the vagina and filled with sarcomatous tissue. Treatment with radium was hopeless though they had had some remarkable results with large polyhedral cell growths and in large round cell tumors. They had treated one woman with sarcoma, proven by operation, where the tumor extended into the broad ligament; she was treated only by raying with massive doses on the surface and through the vagina. Six months later she was again operated upon an another clinic. The pelvis was found normal. When she learned this she wanted to bring suit against the original surgeon on the ground that he had performed an unnecessary operation. In radiating this infant a small applicator was used, but one could get but a short distance into the vagina, and with the finger in the rectum the location of the capsule was determined. There seemed to be some immediate results. In view of the fact that they were unable to tell what was the proper skin dosage they used one-quarter the adult dosage of radium from the outside of the abdomen. However, they apparently hit the correct dosage because there was an erythema. At autopsy a small opening in the culdesac was found, and it was possible that the silver wire punctured the wall of the vagina. Dr. McLean's case was exceedingly interesting inasmuch one of only about a dozen similar cases reported in the literature.

Pyelitis in Pregnancy.—Dr. HARBECK HALSTED presented this paper, which was based on 24 cases of pyelitis during or immediately following pregnancy, occurring at the Sloane Hospital for Women, during the two years from July 1, 1919, to July 1, 1921. He stated that these cases were treated under the direction of Dr. W. E. Studdiford, Director of Sloane Hospital, and Dr. W. E. Caldwell, Associate Director. During the above period there were 3,553 women delivered, making the incidence of pyelitis about 0.7 per cent. Pyelitis was of common occurrence in non-pregnant women and girls, but seemed to be considerably more common during pregnancy. The inciting organisms in this series of cases had been nearly always the *B. coli communis*, mostly alone, but occasionally associated with the streptococcus or staphylococcus, and in one case an unidentified organism closely allied to the *B. coli communis* occurred in pure culture. The route by which the infection reached the kidney pelves was still unsettled. He thought it probable that in different cases different routes were taken by the bacteria. However, infection through the blood stream was probably the most common. The most important contributing cause of the infection seemed, undoubtedly, to be an interference with the free outflow of urine from the ureter with consequent hydroureters and hydronephroses. Most writers on the subject took the attitude that the ureter was compressed by the enlarged uterus, but it seemed to him that a more probable explanation was that it was due to the right torsion of the uterus with some pull on the fascia that supported the uterus, causing a constriction of the lower ends of the ureters as they passed through this fascia. Pyelitis was more common in primiparae than in multiparae. This was probably due to the tearing and stretching of the fascia that supported the uterus by the passage of the first child, rendering the constriction of the uterus less common in subsequent pregnancies. Further contributing causes seemed to be constipation, bad teeth, infected tonsils, or other focal infections. In this series there were two types of onset. First, a slow onset with gradually increasing symptoms; second, an acute onset with a chill, high fever, rapid pulse, and usually a severe pain in one or both costovertebral angles, with usually frequent and painful urination. The above mentioned symptoms with blood or pus and bacteria in the urine should always lead one to suspect pyelitis. If one also had tenderness over the bladder, with or without enlargement of the kidneys, the diagnosis was fairly complete. A culture should always be taken from the bladder and, if there was still any question, the patient should be cystoscoped, the ureters catheterized, and cultures made from the urine from each kidney. They had not hesitated to cystoscope these patients no matter how high the temperature or pulse; although it was probably better to do it in an afebrile period. The cystoscopy with the drainage of the overfilled kidney pelves gave temporary and occasionally permanent relief. The cystoscopic findings were apt to be a bladder that was not very irritable; the walls of the bladder were usually moderately congested with more or less true inflammation, always most marked on the trigone and about one or both ureteral openings. A number of writers claimed that the damming back of the urine in the kidney pelvis was due to a constriction in the ureter caused by inflammation and congestion of the mucous membrane and hence came after and not before the infection. The writer was not entirely prepared to accept this view, because in autopsies on pregnant women who had had no indication of pyelitis during life marked dilatation of the ureters was frequently found. Too much importance should not be placed on a bladder culture, as they were not only often contaminated, but the cultures from the bladder of pregnant and early post partum women often showed a *Staphylococcus albus*, less often a colon bacillus or streptococcus, usually singly, but often together, even when there were no indications of any inflammation. The conditions most often confused with pyelitis were post partum infection, malaria and typhoid fever. The treatment of pyelitis in both pregnant and nonpregnant women was still under discussion, and a great many men differed widely in their management of these cases. They had followed various methods in this series of cases and before, and the following was the procedure they were now following: During the acute symptoms, absolute rest in bed. Raising the head or the foot of the bed, and in the pregnant patient, if strong enough,

the knee-chest posture twice a day for a few minutes. Fluids were forced. Rapid alkalinization of the urine with large doses of alkalies, usually using sodium bicarbonate, a dram every two hours with one-half a dram of sodium or potassium citrate. This treatment often relieved the symptoms, brought down the temperature quite promptly, and cleared the urine of pus; but in none of their cases had they been able to render the urine sterile by these means. After the urine had been kept alkaline for one or two weeks, depending upon the symptoms, they stopped all the alkalies, even in the colon irrigation, and changed to hexamethylenamine and sodium benzoate, giving 10 grains of each every three or four hours. This was kept up for two weeks if the patient showed no signs of bladder or kidney irritation from the hexamethylenamine. After a few weeks of hexamethylenamine and sodium benzoate treatment, they went back to the alkalies, and kept up the alternation until the patient was well and the urine sterile. Urine cultures should never be taken while the patient was taking any of these medicines, especially the hexamethylenamine, as under these circumstances it was practically sure to mislead by being sterile, whereas it really was not as the drug killed the organisms in the test tube. If very soon after the urine became alkaline the patient was not much improved, a cystoscopy should be done and both ureters catheterized and the kidney pelves washed with an antiseptic. They usually used 20 or 30 per cent. solargentum or argyrol. Not more than 5 c.c. should be injected into the kidney pelvis and most of this should be allowed to run off through or around the ureteral catheter before it was withdrawn. This treatment could be kept up from one to three times a week until negative cultures were obtained. There was nearly always an associated cystitis which was treated by the instillation of 5 to 10 c.c. of 20 to 30 per cent. solargentum or argyrol which were allowed to remain in the bladder for ten to fifteen minutes. This treatment was satisfactory in the early months of pregnancy, but in the later months it had been quite unsatisfactory as had all other other methods, with the single exception of the induction of labor or abortion. Colonic irrigations with 2 per cent. sodium bicarbonate if the patient was on the alkalies, or with saline if on urotropin, had seemed to help. If despite all treatment, the patient grew progressively worse the induction of labor or abortion should be considered. This procedure nearly always brought about a rapid change for the better.

Dr. Henry Dawson Furniss said he thought Dr. Halsted had presented the subject very well. He did not believe that pyelitis was limited to pregnancy or that the pyelitis of pregnancy had very few peculiarities differentiating it from pyelitis at other times. He thought the percentage of 0.7 of one per cent. which Dr. Halsted reported was far less than we have had on the gynecological service at the Post Graduate Hospital. There was never a year when there were not quite a number of cases that developed pyelitis after operation. When after operation there was a rise in temperature with no exudate, no wound infection and no respiratory trouble, one should be on the lookout for renal involvement. At times the symptoms might be very slight. There might be just slight pain or discomfort in the back and one would find the patient with her hand under her back. This pain might be elicited by tapping the patient on the back or by deep palpation. This usually lasted only two or three days. Dr. Halsted spoke of the way in which the kidney became involved. He, Dr. Furniss, believed the majority of infections were through the blood stream, but a few showed all the evidence of having ascended along the course of the ureter. There would be a slight temperature, and pain which gradually passed up along the course of the ureter. It was a question whether the infection ascended along the ureter by the way of the lymphatics or was a surface infection of the mucosa. He believed, however, that as a rule infection was by way of the blood stream; the infection was first in the parenchyma and localized later in the kidney pelvis. If lavage of the pelvis was instituted during the first few days the results were not very satisfactory because the infection was still localized in the kidney substance. He did not believe the infection was cleared up so much by the antiseptic property of the drugs as by the active hyperemia that was set up. Dr. Halsted spoke of hematuria and of ecchymotic areas limited to the trigone. It had been his experience that the trigone was no more involved than the rest of the bladder, but if one did a cystoscopy during pregnancy the bladder walls were so collapsed by the pressure of the enlarged uterus that one did not see the entire bladder wall so easily as in the nonpregnant state. One would find ecchymotic areas all over the bladder wall, which made one think the infection an embolic process. In one case of pyelitis in which there was hematuria for one or two days he found on cystoscopy that there were as many as fifty ecchymotic areas scattered over the bladder. He believed most of these infections came through the intestinal tract. Kidd claimed that bacteria were often carried into the blood stream of every individual, and it was only when there was lowered resistance as from exposure to cold, wet, or from excessive fatigue that the organism was unequal to combatting the infection. In the pregnant woman there was greater hydronephrosis than in the non-pregnant, though even in the non-pregnant one found a moderate dilatation of the pelvis and ureter. In treating a pyelitis the pelvis of the kidneys should be well emptied before introducing the medicament. It was important that the pelves of the kidneys be thoroughly emptied as such drainage allowed the pelvis and ureter an opportunity to contract and regain tone. In pyelitis there was a marked swelling of the mucosa and the good effects of drugs was undoubtedly due to their shrinking the mucosa. Dr. Halsted spoke of nephrectomy. He did not think we were as radical in regard to nephrectomy as formerly. Often in pyelitis both kidneys were more or less involved, and we felt that conservatism was safer than taking out one kidney and leaving a slightly damaged kidney. It was not a question of the patient standing the operation of nephrectomy, but of getting well with a remaining kidney as badly diseased as the one removed. There were undoubtedly instances of the fulminating type in which nephrectomy was life saving.

Dr. A. Rongy regretted that Dr. Halsted had been called from the meeting because he disagreed with him and should liked to have had him here. To his mind the etiology of the pyelitis of pregnancy in a very large number of patients could be traced to a latent pyelitis which either complicated or followed the infectious and contagious diseases of infancy and childbirth. Particularly was this true of patients who had had scarlet fever in a severe form. These patients did well when their systems were not unduly strained but when pregnancy took place every secreting organ in the body was overtaxed so that a latent syphilis that had existed for a great number of years very often assumed an acute aspect and showed all the symptoms that were associated with this condition. Pregnancy very often led to a mechanical impediment to the flow of urine through the ureters and in that way caused disturbances in the pelvis of the kidney. He did not see how washing out of the pelvis of the kidney two or three times a week could benefit the patient for the involvement of the tissues was very much beyond where irrigating fluid could reach it. Catheterization of the ureters should be used for diagnostic purposes only. Patients who suffered from pyelitis complicating pregnancy should be kept in a sitting posture as much as possible, for in that way the weight of the pregnant uterus was prevented from pressing upon the ureters at a point where they entered the pelvis. Operative interference was very seldom indicated in this class of patients. If, however, the patient did not seem to improve, as indicated by constant rise of pulse and temperature, labor should be interrupted.

Dr. William H. Wellington Knipe expressed the opinion that the incidence of pyelitis reported at the Sloane Hospital was too low for the reason that they had not reported pyelitis unless a cystoscopic examination had been made. In their series pyelitis was so common that they did not think anything of it. Frequently in cases in which there was a fever during the puerperium he believed there was a pyelitis. At the Gouverneur Hospital he felt confident that the incidence of pyelitis was five times 0.7 of one per cent. easily that. Their treatment differed a little from that at Sloane. They believed in posture and give urotropin, not in 10

grain doses which they thought inadequate, but in 60 grain doses daily and enough acid sodium phosphate to make the urine completely acid. The head of the bed was raised and fluids were forced, and 60 grains of urotropin daily were administered. If one did this there would be little need for other treatment. That was their experience. With this treatment they had had no occasion to employ lavage of the kidney. They had had cases in which they had used vaccines, ordinary stock vaccines, and the patients had responded to the treatment. Dr. Knipe thought conservative treatment was better in these cases. The temperature curve might keep up for some days, but he had never seen one of these patients who required operative interference. If treated conservatively these patients all got well.

Dr. HERMAN LORBER recalled that Dr. Halsted had said that the differential diagnosis of pyelitis was quite easy. He knew of a patient seven months pregnant who had pain and rigidity in the lower right quadrant and ran a temperature of 103°. The doctor who attended her assured him that the urine showed no pus cells. She was taken to the Hospital and the blood count should a high differential count. An operation for appendicitis was performed and a perfectly normal appendix removed. A catheterized specimen of urine later showed pus cells. The woman was delivered two months later and made an uneventful recovery. Attention might be called to the fact that pyelitis might cause symptoms very similar to those of appendicitis.

Dr. HARVEY B. MATTHEWS stated that he had had two cases similar to the one just reported in which the symptoms were those of appendicitis, though fortunately the patients were not operated upon. The diagnosis of appendicitis in one case was made by two surgeons and two general practictioners and in the other by two surgeons only. In a third case Dr. Humpstone made the diagnosis of pyelitis in a woman six months pregnant just as she was being prepared to be taken to the hospital for an operation for appendicitis. In one of the first two cases mentioned operation was advised but was delayed. In a short time both patients recovered.

Dr. WILLIAM P. HEALY said he was much interested in Dr. Halsted's paper, especially since it covered such a large number of cases studied so carefully. He was especially interested in the discussion on the treatment of pyelitis because some years ago he heard Dr. Furniss say that practically all cases of pyelitis should be treated by lavage of the kidney pelvis. His experience up to that time had been so uniformly favorable by simple medical treatment without cystoscopy or lavage that he was very firmly opposed to his point of view, but in the last two years he had had three cases which did not respond to the most approved methods of medical treatment in the effort to relieve the pyelitis, and relief was only obtained by catheterization and lavage of the kidney pelvis and then they were so promptly relieved that he was now quite convinced that some cases had to have that done in order to be cured. He had never had a case of pyelitis that had to have labor induced but he thought, as Dr. Halsted had said, that if the condition of the patient became serious that might sometimes be necessary.

Dr. BAILEY said he wished to bring out a point merely for reiteration. For years they had all adopted the conservative method of treating pyelitis. As Dr. Healy had said there were very few of these cases in which the kidney pelvis had to be emptied by catheterization. The whole question was what happened to the woman later on; did she develop pyelonephritis or was she cured? Merely because she had no fever did not mean that the pyogenic bacteria had been entirely eliminated. Many might continue to have pyogenic bacteria who felt comfortable and well. Another important point was the administration of all these drugs. He questioned the advisability of giving these drugs for three or four weeks; hexamethylenamine for two weeks and alkalies for two weeks. He did not see how the stomach could tolerate such treatment for such a length of time, especially when acid sodium phosphate was combined with urotropin.

Dr. W. E. CALDWELL said the point had been brought up as to a history of scarlet fever in these cases of pyelitis. In this series of cases Dr. Halsted tried very hard to get a history of previous pyelitis during childhood. He thought they all had the idea that a great many cases of pyelitis developing during pregnancy had their start in childhood. In this series of cases only three gave a history of pyelitis. The incidence of 0.7 per cent. was a surprise to them all. They had expected to find it a great deal higher, but, as Dr. Halsted said, these were cases in which the pyelitis was proved by cystoscopic examination and bacteria were obtained from the pelvis of the kidney. In all cases that ran a temperature, a catheterized specimen of urine was obtained; in this way they had tried to get all the positive cases of pyelitis though possibly some were skipped. As to the treatment, he thought they were all agreed in regard to the advantage of keeping the patient in the upright position or in raising the head or foot of the bed to relieve the pressure on the ureters. The washing out of the pelvis of the kidney was not undertaken until medical treatment had been given a good chance to succeed. It had been rather astonishing how quickly in some of these cases in which medical treatment failed the urine cleared up after cystoscopic examination. Frequently on catheterization one obtained a large amount of urine filled with pus and the temperature came down to normal and remained so. If the temperature rose again the cystoscopy was repeated and drainage again established. Dr. Halsted had followed some of these cases for two years. There were only two cases that he was successful in making bacteria-free during pregnancy. In none of those cases in which the bacteria remained for a long time in the pelvis of the kidney without treatment outside of the ordinary medical treatment, did he succeed in making the urine bacteria-free. Eight of the 24, if he remembered correctly, showed exacerbations afterward and only by intensive treatment, putting argyrol in the pelvis of the kidney, did he finally succeed in getting them bacteria-free. Sodium bicarbonate and urotropin were rushed until the urine became alkaline and then just enough of these drugs was given to keep it alkaline. If the temperature did not come down they changed to acid sodium phosphate for a short time.

Pregnancy After Nephrectomy.—Dr. HARVEY B. MATTHEWS made this presentation, in which he said it was well known that after nephrectomy for any cause there was a compensatory hypertrophy of the other kidney, so that the urinary function was not decreased for any length of time after operation, and frequently this hypertrophy had taken place before the diseased kidney had been removed. Physiologists told us that the total amount of renal tissue possessed by normal individuals was three to four times what was actually needed to meet the ordinary demands of the organism. While chemical and microscopical examination following nephrectomy usually revealed complete return of renal function, in some instances this was not the case. In a goodly number of nephrectomized individuals albumin was present in the urine many years after nephrectomy. In about 25 per cent. of cases of nephrectomy for unilateral renal tuberculosis there was an abnormal condition of the remaining kidney, as was shown by albumin in the urine, irritable bladder, etc. For years there had been the feeling that pregnancy was greatly to be feared in a woman who had had a nephrectomy. In view of these facts the writer had made a study of 200 cases from the literature in which pregnancy occurred following nephrectomy; 37 cases collected in Greater New York, and 4 cases coming under his personal observation. Before analyzing this series of cases it might be noted that there were two classes of cases in which nephrectomy was performed. In one it was done for pyonephrosis, pyelonephrosis, benign tumor or cyst; in the other for unilateral renal tuberculosis or malignant disease. In the former group the remaining kidney was much more likely to be competent and remain so than in the latter. In the 200 nephrectomized patients collected from the literature there were 215 pregnancies, in 10 of which there were complications, and 2 died. In the 37 cases in Greater New York there were 43 pregnancies; five of these pregnancies were complicated by severe toxemia. In the writer's four cases nephrectomy was performed three times for unilateral tuberculosis and one for pyonephrosis; all of these patients had albumin in the urine ranging from 1 to 4 plus. These four nephrectomized

women had seven pregnancies and seven living children, with no serious complications. Blood chemistry observations in three of these women, as compared with three non-pregnant women with only one kidney showed the urine to be normal. Taking these cases all together there was a total of 265 pregnancies with 250 normal labors and two deaths; and 15 labors in which there were complications. From a study of these cases it would seem that pregnancy in the nephrectomized woman was little more hazardous than in normal women, provided the remaining kidney was functioning properly. Albumin occurred in a certain proportion of these cases, usually in the latter months of pregnancy, but if treated properly cleared up just as in the normal case with two kidneys. In 60 per cent. of the cases studied there was albumin from 1 to 4 plus during the latter weeks of pregnancy. Some of the nephrectomized women had albuminuria all through pregnancy. There was little to be said regarding the conduct of labor in nephrectomized patients. They stood morphine and anesthesia well. Chloroform, of course, should never be used for reasons needing no elucidation. Chloral hydrate and veronal were badly borne by these patients. Lactation was not interfered with in nephrectomized women, but if the nephrectomy had been done for unilateral tuberculosis of the kidney lactation should be prohibited. Marriage after nephrectomy was permissible if the remaining kidney has functioned normally for one year or more. If there were symptoms of renal insufficiency in the remaining kidney after marriage, pregnancy should not be allowed to take place and contraceptive methods should be employed. If nephrectomy had been performed for unilateral tuberculosis of the kidney pregnacy might be permitted provided the remaining kidney had functioned normally for three years or more. If nephrectomy had been performed for a malignant tumor pregnancy must never be permitted. Finally there was need of a full study of nephrectomized women with well worked up reports of urinary findings and blood chemistry on every case of pregnancy after nephrectomy.

Dr. A. RONGY stated that this paper would be very useful to those who practised obstetrics, for very little had been written on this subject by English or American clinicians. He recalled the first patient who came to engage him for her confinement and who told him one of her kidneys had been removed some three or four years previous to this time. He really was reluctant to accept her. Evidently he was not familar with the literature on the subject. However, in looking up the literature, he found there really was no cause for alarm, which practically coincided with what Dr. Matthews had said tonight. He had had three cases of pregnancy and labor in patients with only one kidney. In two the kidneys were removed for benign tumors and in one for tuberculosis. One of these patients had a great deal of albumin during the early period of pregnancy which gradually diminished until she reached the ninth month, when it reappeared in large quantities. At one time when the urine contained no albumin she passed as much as 120 ounces of urine in twenty-four hours. Dr. Rongy recalled a patient telling him that she had had seven children after one of her kidneys had been removed. On the whole it seemed that these patients stood labor and pregnancy very well.

Dr. W. E. CALDWELL said it was interesting that so many women who had had nephrectomy should go through pregnancy and labor with so little trouble. They could furnish another instance. They had had a patient who had had a nephrectomy and two subsequent pregnancies. This woman had had a nephrectomy for a perinephritic abscess. She had eclampsia both time. There was four years between the pregnancies. The interesting points in this case were that the systolic blood pressure was 220, the urine boiled solid while the blood chemistry was but slightly changed. After delivery the blood pressure dropped to 118 or 120 and the urine cleared up.

Dr. ALFRED M. HELLMAN cited a case of pregnancy following nephrectomy for tuberculous kidney that was now under his observation. The right kidney had been removed eight years ago. She was married five years ago and had a child 3½ years old. She was now in the fourth month of her second pregnancy and had had no complications in any way related to the nephrectomy. She had a slight uterine hemorrhage during the second month. She had had no albumin in her urine, and her systolic blood pressure had ranged from 95 to 110. He had been seeing her every week since early in July.

Dr. BAILEY stated that one of the cases reported in Dr. Matthews' paper was very interesting. When there was an elevation of the nonprotein nitrogen and high uric acid in the blood it was almost certain that the woman had a badly damaged kidney. One could estimate the years of life on the basis of such findings. In cases in which the total nonprotein nitrogen went above 100 the patient had a very short time to live.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

ACTA SOCIETATIS MEDICORUM FENNICAE DUODECIM Tom. III Fasc. 1-2; Tom. II Fasc. 2-3; Tom. III Fasc. 1-2. Published by S. E. Wichmann (Editor) at Helsingfors, 1921.

SOLUTIONS—A Text Book for Nurses. By ELSIE M. SMITH. 59 pages. Price, $1.00. Published by C. V. Mosby Company, St. Louis.

SYNOPSIS OF MIDWIFERY. By Dr. ALECK W. BOURNE. 211 pages. Price, $3.50. Published by William Wood & Company, New York.

ANNEXITES NON INFECTIEUSES. By Dr. PAUL DALCHE. 54 pages. Price 4 francs. Published by L'Expansion Scientifique Française, Paris.

CLINICAL DIAGNOSIS. By Dr. C. P. EMERSON. Fifth edition. 726 pages with 156 illustrations. Published by J. B. Lippincott Company.

VICE AND HEALTH. By JOHN C. FUNK. 174 pages. Price, $1.50. Published by J. B. Lippincott Company, Philadelphia.

EPHRAIM MCDOWELL. By AUGUST SCHACHNER, M.D. 350 pages with illustrations. Price, $5.00. Published by J. B. Lippincott Company, Philadelphia.

ACUTE EPIDEMIC ENCEPHALITIS. By the Association for Research in Nervous and Mental Diseases. 258 pages with illustrations. Price, $2.50. Published by Paul B. Hoeber, New York.

THE SURGICAL CLINICS OF NORTH AMERICA, October, 1921, Vol. I, No. 5 (Mayo Clinic Number). 296 pages with illustrations. Price, $12.00 per year (6 Nos.) Published by W. B. Saunders Company.

DISEASES OF THE DIGESTIVE ORGANS. By Dr. CHARLES D. AARON. Third Edition. 904 pages with 164 engravings, 48 roentgenograms and 13 colored plates. Price, $10.00. Published by Lea & Febiger, Philadelphia.

EXOPHTHALMIC GOITRE. By Dr. WALTER EDMUNDS. 34 pages with illustrations. Price, 3s. 6d. net. Published by Balliere, Tindall & Cox, London.

THE SOCIETY OF THE NEW YORK HOSPITAL, Commemorative Exercises. 96 pages with illustration.

LES GRANDES FORMULES MODERNES DE LA NUTRITION. By TH. MERRILL and H. VIOLLE. Pamphlet of 12 pages. Published by Masson & Cie, Paris.

THE RELATIONS OF TUBERCULOSIS TO GENERAL BODILY CONDITIONS. 27 pages. Price, 2s. 6d. paper cover. Published by H. K. Lewis & Company, London.

EPIDEMIOLOGY AND PUBLIC HEALTH. By VICTOR C. VAUGHAN. Vol. I. 688 pages with illustrations. Price, $9.00. Published by C. V. Mosby Company, St. Louis.

ESSENTIALS OF LABORATORY DIAGNOSIS. By F. A. FAUGHT. 523 pages with 11 plates and 78 engravings. Price, $4.50. Published by F. A. Davis Company, Philadelphia.

SUBMUCOUS RESECTION OF THE NASAL SEPTUM. By WILLIAM M. DUNNING, M.D. 97 pages with illustrations. Published by the Surgery Publishing Company, New York.

Medical History.

NEW BOOKS AND OLD

XXII. REGIMEN SANITATIS AND THE SALERNE SCHOOL.

By JOHN RUHRÄH, M.D.,

BALTIMORE, MD.

A NEW edition of the famous Regimen Sanitatis Salernitanum is a most welcome addition to medical letters, for in spite of some two hundred and forty odd times this work has been printed, it remains a rare book, more or less difficult to obtain and there are but few libraries boasting many copies. Any book that has approached a quarter of a thousand editions in various languages must have some merit. The one in question has so much that for centuries it was one of the chief sources of information on the subject of hygiene and diet. Now it has passed into a literary curiosity not very well known except to medical and other literati. To appreciate the school of Salerno we must go back to a monastery founded by Saint Benedict on the slopes of Mt. Cassino which is about midway between Rome and Naples. Saint Benedict is one of the outstanding figures in medieval Europe. To properly understand medicine in Europe in the middle ages, I would suggest the reading of Henry Adams' "*Mont St. Michel and Chartres.*" This gives one the atmosphere of the time; a few facts and the imagination do the rest. At Mount Cassino, Benedict founded a large monastery which had a stormy career. First it was sacked by the Lombards, then by the Saracens, but after being rebuilt a third time it took on new life, wielded an enormous influence survived until 1866 when it was declared "A National Monument" in which a school is maintained. The Library still has over 10,000 volumes, amongst them many early treasures of great rarity, to say nothing of manuscripts, papal bulls and similar material of extraordinary historical interest.

At Mount Cassino the Benedictines in the old days nursed the sick, and many the celebrated traveller who sought aid at the shrine and who, if the tales are to be believed, went away not unrewarded. A curious lot of stories are recorded. One tells how the Emperor Henry II of Germany while there fell into a deep sleep during which St. Benedict caused a bladder stone to disappear.

Despite the orders of Saint Benedict the monks not only cured but taught and more than one became a medical writer. Here Constantine, the African, eventually found refuge and devoted his days to translating, editing and writing. Largely through him flowed the channel of Arabic and Eastern medicine into Europe.

Far to the south lay a city of ancient lineage, Salerno, a smiling sea at her feet, behind her a pine clad mountain to temper the winds and perfume the air. Tradition has it that Salerno was one of the five cities founded in Italy by Shem, the elder son of Noah. The town dates back to the earliest time. In 194 B.C. it was a Roman colony and doubtless many of the later movements of peoples, as the Goths, the Lombards and others left traces in the place so favorable to health.

The Benedictines founded one of their monasteries in Salerno and soon the place was filled with shrines, physicians, students and patients. The crusaders and others carried the name throughout Europe, and the saying was *Urbs antiqua Salernum, celebrata per orbem.*

There were the usual shrines, the usual relics, the usual wonderful cures, the usual tales about them. Perhaps the most important shrine was that of St. Matthew, the patron saint of the town to whom Robert Guiscard erected a cathedral in 1070 after he captured the castle above after an eight month siege.

Salerno was far enough south to come within the sphere of Greek influence and the cast mantle of Hippocrates may be said to have in part made up the garb of the physicians who in their school carried out, at least to a certain extent, the Greek traditions. This is not the place to go into any extensive account of the authors of Salerno. Their names have an unfamiliar sound to most of us: Johannes Afflacius, two Cophons, Ferrarius, Archimatheus. The last named left some directions for the conduct of physicians, part of which are quoted from Daremberg in the introduction by Francis R. Packard in his introduction in the new edition. Platearius, Musandinus, and the celebrated Gilles of Corbeil (Aegidius Corboliensis) author of poems on the pulse and on the urine came later as did The Surgeons Ruggiero of Palermo and Rolando of Parma. These and others gave a lasting fame to the school of Salerno. In many of the writings occurs the phrase *mulieres Salernitanae* which has been politely rendered "the ladies of Salerno." To us moderns perhaps these women physicians are among the most interesting of the manifestations of the time of this medical school. A short but satisfactory account will be found in Withington's History of Medicine. Trotula was the most renowned, but one reads of Sichelgaita, wife of Robert Guiscard and of Stephonia with more interest. Their lives would make lurid moving picture scenarios. The last named lady's husband was killed by Emperor Otto III. She ensnared the Emperor and when ill cured him only to wrap him during his convalescence in a deerskin covered with corrosive poisons, so he died in great agony. But we must hurry on. Longfellow in his Golden Legend deals with the story of Salerno.

This legend was the story of Henry the Poor, Prince of Hoheneck, who became a leper and left his castle to dwell in retirement. He was told that he could not be cured until a spotless virgin was willing to die for him. The daughter of the farmer with whom he lived offered herself and the prince finally consented to accompany her to Salerno. On his arrival he found that he was cured so he married the maiden in the great cathedral. The many other interesting stories must be passed over.

One should not fail to read the account of Salerno as given in an essay by Sir Clifford Allbutt read to the Erasmus Club in Cambridge 1912. This may be found in the volume of his essays entitled: "Greek medicine in Rome."

The new edition is printed by Paul Hoeber, is dated 1920 and is a reprint of the English version by Sir John Harington. It is edited by Francis Packard who contributes "A History of the School of Salernum." Packard's account of the history of the school of Salerno is followed by a short essay

by Fielding H. Garrison entitled "Note on the Prehistory of the Regimen Sanitatis." He shows that "the School of Salerno was of purely laiacal character, a *Civitas Hippocratica* in the midst of monastic foundations." As Garrison says the tendency of the period was to collect scraps and stitch them together and pass off the resulting treatise as original. This he believes was the origin of the *Regimen Sanitatis*, which started with 362 verses, which Arnold of Villa Nova edited with notes. Subsequent additions raised the number of verses to 3520. Sudhoff believes that the poem had its origin in a prose epistle of Aristotle (De conservatione corporis humani) written for Alexander the Great, as many of the sayings are strikingly alike. It was not until the middle of the 13th century that the poem became generally known. Concerning the various editions: Sir Alexander Croke and Daremberg both give extensive bibliographies which may be consulted by those interested. The first translation into English, unless I err, was made by an Austin Friar, Thomas Paynell in 1528, who stated, "That this boke techying al people to governe them in helthe is translated out of the Latyne tongue in to Englyshe." Thomas Phaer who wrote the first book on the diseases of children to be printed in English made a prose translation from the French. This must have been popular as it was reprinted many times. Packard reprints the Latin text as published in 1830 by Croke. Another accessible Latin text is that of Zaccharias Sylvius, originally printed at Rotterdam in 1657 and reprinted by Dr. John Ordronaux in his poetical translation published in 1870.

Now as to the poem itself. It would take a volume to consider the various texts, editions and translations. The first printed edition appeared, presumably at Montpellier in 1480 with a commentary by Arnold of Villa Nova. This has been issued in the *original* Latin in 107 editions according to Ordronaux. It was first translated into German in 1474, into French in 1501, Italian in 1549, Dutch in 1658. In all some 165 or more editions have appeared. The Ordronaux volume is a delight. It gives the Latin on one page and the translation on the page facing. The introduction is full of interesting material. Ordronaux gives some account of the Leonine or rhyming verse, a subject that has been considered in detail by Sir Alexander Croke in his "Essay on Rhyming Latin Verse." In an appendix he gives the additions made to the text of Arnold of Villa Nova as given by Daremberg in his Paris edition of 1851. He also gives specimens of early English metrical translations as follows:

SPECIMENS OF THE ENGLISH TRANSLATIONS, OF WHICH THERE APPEAR TO HAVE BEEN THREE HERETOFORE MADE, VIZ: A. D. 1575, 1607, AND 1617.

The first, from a MS. in the library of Corpus Christi College, Oxford, dated 1575:

"The puisante Kinge of Brittannye
The schole of famous memorye,
Salernum, biddes him selfe to frame,
If healthe he woulde and kepe the same;
Geve cares noe place within thy brest;
Lett fretting furies be supprest;
Too muche of wine use not to swill;
Suppe you but lighte, eate not thy fill;
At meate to sitte soe longe a time,
To rise is not soe greate a crime;
At noone geve not thye selfe to slepe;
Nor use thye water for to kepe.

"He maye that liste this to observe,
Him selfe longe time in healthe preserve.
When physicke harde is to be hadd,
Three things may be in steede.
The minde in noe wise must be sadde,
Meane reste and diette muste thee feede."

The second, called the Englishman's Doctor, London, A. D., 1607: (This is the translation by Harrington).

"The Salerne Schoole doth by these lines impart
All health to England's King, and doth advise
From care his head to keepe, from wrath his harte.
Drink not much wine, sup light, and soone arise.
When meat is gone long sitting breedeth smart;
And after noone still waking keepe your eies,
When mou'd you find your selfe to nature's need,
Forbeare them not, for that much danger breeds,
Use three physitians still—first Dr. Quiet,
Next Dr. Merry-man, and Dr. Dyet."

The third, called the Regiment of Health, London, 1617:

"All Salerne Schoole thus writes to England's King,
And for men's health these fit advises bring.
Shunne busie cares, rash angers, which displease;
Light supping, little drinke doe cause great ease.
Rise after meate, sleepe not at afternoone,
Urine and nature's neede, expell them soone.
Long shalt thou live if all these well be done.
When physicke needes, let these thy doctors be,
Good diet, quiet thoughts, heart mirthful, free."

To these may be added Ordronaux's translation:

"Salerno's School, in conclave high, unites
To counsel England's King, and thus indites:
If thou to health and vigor wouldst attain,
Shun weighty cares—all anger deem profane,
From heavy suppers and much wine abstain.
Nor trivial count it, after pompous fare,
To rise from table and to take the air.
Shun idle, noonday slumber, nor delay
The urgent calls of Nature to obey.
These rules, if thou wilt follow to the end,
Thy life to greater length thou mayst extend."

Sir John Harrington's edition was first published in 1607. He was considerable of a writer and as Packard says: "one of the most characteristically Elizabethan of the courtiers of Queen Elizabeth." His writings are said to have a leaning to what we would now perhaps style the Gallic tendency. There is an article by Adami on Harrington in the Johns Hopkins Hospital Bulletin for October, 1908, from which may be gleaned the fact that he invented the modern water closet which is described in a monograph entitled "A new Discourse of a Stale Subject called the metamorphosis of Ajax, London 1596.

It is conjectured that Harrington made his version in connection with his part in the education of Prince Henry. A considerable number of Harrington's verses are still extant and several of his epigrams are well known, for example his rendering of Martial's epigram:

The goodly haire that Galla weares
Is hers; who would have thought it?
She swears it is, and true she swears,
For I know where she bought it.

and also the following:

Treason doth never prosper; what's the reason?
Why; if it prosper, none dare call it Treason.
* * * * * *
Books give not wisdom where was none before
But where some is, there reading makes it more.

The following are some specimens of Harrington's translation:

"They that in Physick will prescribe you food,
Six things must note we heere in order touch,
First *what it is*, and then *for what 'tis good*.
And *when* and *where*, *how often*, and *how much*:
Who note not this, it cannot be with-stood,
They hurt, not heale, yet are too many such."

* * * * * *

"To keepe good dyet, you should neuer feed
Vntill you finde your stomacke cleane and void
Of former eaten meate, for they do breed
Repletion, and will cause you soone be cloid,
None other rule but appetite should need,
When from your mouth a moysture cleare doth void.
All *Peares and Apples, Peaches, Milke and Cheese,
Salt meates, red Deere, Hare, Beefe and Goat:* all these
Are meates that breed ill bloud, and Melancholy,
If sicke you be, to feede on them were folly."

* * * * * *

"Chuse wine you meane shall serue you all the yeere,
Well-sauor'd tasting well, and coloured cleere.
Fiue qualities there are, wines praise aduancing,
Strong, Beautifull, and Fragrant, coole and dancing."

* * * * * *

"Some loue to drinke new wine not fully fin'd,
But for your health we wish that you drinke none,
For such to dangerous fluxes are inclin'd,
Besides, the Lees of wine does breed the stone.
Some to drinke onely water are assign'd,
But such by our consent shall drinke alone.
For water and small beere we make no question,
Are enemies to health and good digestion:
And *Horace* in a verse of his rehearses,
That *Water-drinkers* neuer make good verses."

* * * * * *

This last may be taken as evidence that Mr. Volstead would not have been popular in Salerno.

"But here the *Salerne Schoole* doth make an end:
And here I cease to write, but will not cease
To wish you liue in health, and die in peace:
And ye our Physicke rules that friendly read,
God grant that Physicke you may neuer need."

* * * * * *

The above may be compared with some of Ordronaux's verses. Comment is not necessary.

FOOD TO BE AVOIDED.

"The luscious peach, the apple and the pear,
Cheese, ven'son, salted meats and e'en the hare,
With flesh of goats, dyspeptic throes provoke,
And crush the weak 'neath melancholy's yoke.

(*Addition* from Paris Ed., 1861.)

"Salt is the flesh of ruffled ducks and geese;
Fried meats do harm; while boiled give peptic peace;
And fragrant roasts, digestive powers increase.
Bitters will purge—crude things in all cause wind,
And salted meats the body dry and bind,
While crusts give rise to bile of darkest kind.
Salt things consume virility and sight,
And psoric torments breed of direst might."

* * * * * *

OF THE QUALITIES OF GOOD WINE.

"The taste of wines, their clearness, odor, shade,
Are living proofs of their specific grade;
You'll find all those that are of highest source,
Fragrant, frigid, fair, fuming with high force."

* * * * * *

OF MUST.

"New wine at once doth diuretic prove,
And sluggish bowels tends to freely move;
The spleen and liver causes to congest;
And sometimes, too, incites a lithic pest."

OF DRINKING WATER.

"Who water drinks at meals hath mischief brewed;
The stomach chilled voids undigested food."

(Addition A. V.)

"Let men drink wine, let beasts for fountains crave,
But water-drinking never men enslave."

* * * * * *

OF DIETING.

"Doctors should thus their patient's food revise—
What is it? *When* the meal? And what its *size?*
How *often? Where?* lest, by some sad mistake,
Ill-sorted things should meet and trouble make."

* * * * * *

VALEDICTORY.

"The Flower of Physic endeth here its strain;
The Author, happy o'er his garnered grain,
Prays that in Heaven there be prepared for him,
A seat near Christ, and His blest Seraphim.
Amen!"

* * * * * *

A Medical School at Teheran.—Porak describes a new medical school in the Persian capital which will be largely under the control of French instructors (*La Presse Médicale.*) He went to Persia at the instance of the Government of that country, only to learn that the supposed Persian Medical College existed on paper only. There is an excellent hospital which was created by the Germans and after the war passed into the hands of the English. This occupation seemed to extinguish the local college, for the English took over the treatment of all the sick. The old faculty, which comprised Persians and French, found their occupation gone. The author will endeavor to reorganize the medical college along the usual lines of colonial institutions. At present it would be unethical to give diplomas to students who have had no dissection and who have never examined a patient. For eight months he has been striving to organize a new hospital for clinical instruction. Persia is essentially a country of French culture and French is spoken next in frequency to Persian. There are three French colleges in the country. German instruction has passed out, and under English instruction the author only mentions that the American College attracts the children of the aristocracy. Negotiations just now are in a critical condition, but Porak believes that his dream of a first class Franco-Persian Medical College will come true.

French Kings Proclaiming Against Infanticide.—In February, 1556, King Henry II of France issued a manifesto to the childbearing women of his realm in which he claimed to have been informed of the existence of an enormous and execrable crime of frequent occurrence by women, who, having conceived, whether honestly or dishonestly, through bad intent or bad counsel, suppressed the fact of pregnancy and when delivered disposed murderously of the child without the formality of baptism. Burial of these children took place in unconsecrated soil. Women of this kind when brought before tribunals asserted that their infants were stillborn and it was often impossible to disprove this assertion. The Judges could not agree on the course of procedure. Women who had been accused of this offence seemed prone to repeat it. The proclamation of the King for the suppression of this offence dealt chiefly with the necessity henceforth for valid witnesses of stillbirth, while concealment of gravidity was made an offense. Neglect of baptism and public interment in the case of a deadborn infant was also made felony punishable with death. The proclamation was made by criers throughout the entire realm and also was read publicly in churches. —*La Presse Médicale.*

THE USE AND ABUSE OF LOCAL SUPPORT ALSO MOTOR REEDUCATION IN HUMAN READJUSTMENT OR ORTHOKINETICS.

BY J. MADISON TAYLOR, A.B., M.D.,

PHILADELPHIA, PA.

PROFESSOR OF PHYSICAL THERAPEUTICS AND DIETETICS, MEDICAL DEPARTMENT, TEMPLE UNIVERSITY.

THE resources of fixation rest are here presented as they arise in problems of internal medicine as well as in inflamed, injured, defective, relaxed, paretic, disabled or painful structures, direct or associated, along with remedial devices and methods which can be recommended. They serve as valuable agencies for supplying conditions and positions of advantageous purposive movement. The author, while not a surgeon, has devoted his attention constantly to the reestablishment of functional equilibrium through readjustments of structure.

The prime objective of one who would raise the coefficient of efficiency to the highest point in any individual is to reestablish poise, harmony in all common and uncommon energy manifestations. This includes readjustments of the static and skeletel muscles, the release of intraarticular pressures and of all structures capable of being brought under control of consciousness, both the cerebral and the cellular. In particular it is desirable to cultivate the conditioned, the reasoned, or trained reflexes, hence self-mastery of structures and cellular consciousness.

Behind all lies the background of body chemistry, a factor of direct significance here since movement, conscious purposive movements, and all the motor elements in functional integrity depend in chief measure upon balanced nutrition and the motor functioning of the digestive mechanisms.

Organic disharmony—no matter what be the original cause or causes incriminated—is the product of inadequacies in the muscles as accessories to, or essentials in, all functioning, coarse or fine. As a crude illustration, we may cite such disharmonies as are the outcome from imbalances in any or all motor structures, in the vasomotor, the ideomotor, and accessory motor mechanisms. In short, ideal reparative conditions are realizable in proportion as this motor, emotor, vasomotor, or ideomotor reflex poise is secured and maintained.

The principles of structural, organic, reflex, and cerebral adjustment rest on the same basis—the organism being a composite of physiogenic and psychogenic factors, in that nice or harmonious interdependency which connotes health. In this hierarchy the cellular, the structural, especially the muscular, factors are as important as the metabolic or grandular or cerebral or any other physiologic grouping or concatenation.

In short, until the static, skeletel, semivoluntary muscles and their accessories, the bones, joints, ligaments, white fibrous structures, and other mechanisms of adjustability—automatic or purposive—are in advantageous correlationship, the one to the other, then are the processes of life—as commonly visualized— not capable of stabilization or the maintenance of functional poise.

Localized rest through support or temporary fixation serves so many valuable purposes and in so wide a variety of disabilities sensory or motor, that the topic deserves consideration by all clinicians.

The surgeon has constant need of supplying local support, or immobilization; the internist equally so, though more rarely. He too should acquire the habit of thinking in terms of biophysics and of biokinetics, in order to deal adequately with many exigencies coming within his jurisdiction. Best results can in many instances, follow only through the use of such fixation instrumentalities.

These suggestions are offered especially to the general practitioner, in particular the man who operates upon the borderline between the surgeon and the internist. To understand, to diagnose, and to apply these instrumentalities with the best effect becomes so great a nicety as to approach a fine art.

The principles governing pathology and the economics of functional restoration are similar in like problems. The rôle of the reflex irritation or exhaustion, over-action, under-action on anomalous action, *e.g.* tonic spasm or motor inadequacy, are intimately concerned. So are problems of parts held in positions of disadvantage, which require restoration to positions of advantage, likewise involved. Structures in positions of advantage not only act better but, when impaired, recover better upon being placed and held in positions of best advantage. This is true of all structures, soft as well as static or rigid.

Pain on movement, active or passive, is in most instances the indicator, while in others it is a mere disability, which disability may become permanent unless structural competence is skilfully and promptly conserved. Here also is the psychogenic factor of voluntariness or inadequacy to be adjusted.

Associated structures oftentimes are able to act, or be made to act, as support or reinforcement. They may do so, however, to the disadvantage of

the impaired structure. Hence it is frequently necessary to put the supplemental structures temporarily out of commission in order adequately to restore the tone of those impaired. This is an especially important precaution to be taken in the pareses, such as in poliomyelitis. The more powerful antagonist becomes thus a menace. Its excessive action must be restricted by some device or the less capable muscle is over-worked and suffers aggravated impairment.

Health is well visualized as a nice state of poise between all the energies arising from within or without, of the readjustments from unfavorable to favorable, whereby a relative balance or harmonious interaction is maintained.

The tone of muscles varies widely, not only in different muscles at the same time, but under differing times and circumstances. Among the causes for this variation are : defective original development, differing states of energy, of action patterns, of control, of degrees of acquired causation through disuse, disease, injury, or through inadequate care during convalescence. Reflex arcs (or circuits) vary widely in their capabilities for sustained functioning, they become wearied, stressed or exhausted, and then demand full rest.

The term support is here used in the sense of an upholding, or reinforcing, or sustaining of the load to be carried—the work to be done—in accord with function and design. Also in the broader sense of restoring to positions of advantage those structures whose duties are to carry a maximum load and then a little more ("the factors of safety") and thereby subserve collateral as well as direct functions.

A natural support is whatever associated parts are qualified by design to sustain or to contribute to the tensile or static power of the framework—bony, ligamentous, tendinous, fibromuscular, muscular, parenchymatous or dermal, also the maintenance of intraorganic, or intraarticular pressures. Here we have the several and the total (sum of) factors which make for *position*, interrelationship, posture, whereby function or proficiency is best subserved. The objective is always to restore normality in the tone of affected structures. *Attitude* is the adjustment assumed naturally (purposively or instinctively) in accord with design, that which is assumed by conscious or subconscious choice.

An artificial support is a device adapted or applied to meet the particular needs of a part which, for one reason or another, is no longer able to carry or handle its customary load. The causes and conditions making such aid necessary may be (as mentioned) a primary defect (developmental), or a secondary defect, stress or disorder, disease, inflammation, paresis, injury, fracture, strain, sprain, or functional or nutritional or psychogenic disorder, or faulty habits leading to the assumption of disadvantageous positions (or attitudes) of a part or associated parts. Note the element of reflex arc (circuit) exhaustibility also.

Collateral or secondary causes (*e.g.* overstress) must likewise be reckoned with; among these are shock, fright, exposure, fatigue, causing disorder or disrepair of one part, throwing stress, fatigue, or strain upon associated parts, whereby conscious control is inhibited, bewildered, causing transferred pains, tonic spasm and the like. Also the whole organism, the sum total of essential energies may have become lowered beyond the edge of the factors of safety, hence occurs collapse.

Support, or immobilization, is oftentimes required during acute disease, especially in irritable, tender, painful, inflammatory, or spasmodic conditions, such as rheumatic fever, pleuritis, poliomyolitis, neuritis, in diseased states of the circulation, or respiration, of digestion, of the abdominal organs, of genito-urination, or reproduction, and the like. Also anomalous conditions arising during acute exacerbations of protracted diseases, especially in joints (arthritis, periarthritis, excess intraarticular pressure), likewise of muscles and fibrous structures, fibromyositis, gouty states; also in old foot troubles, such as weak arches, metatarsalgia, and in many other disablements.

Support or fixation is particularly helpful in many protracted disorders, and is frequently demanded during the progress of various chronicities. In many instances support affords the only instrumentality capable of encouraging depressed function; thus it contributes both directly and indirectly to harmonies and completenesses of functioning (*e.g.* in cerebral or in splanchnic circulation). Also in the extensive group of disorders due to impairment of vascular tone or vasomotor integrity (blood ptosis of C. Ward Crampton). Note the variants in maximum systolic pressure in the lying, sitting, and standing attitudes.

The dominant groups of organic activities can only be expected to perform thoroughly or economically when those structures which supply support are, and remain, in tone. The tone or power of tonal sustension must be adequate in order that the part shall fulfill function.

The care and after care of a large proportion of disorders, and the deteriorating effects of disease, can be carried to legitimate conclusions only by restoring tone in the correlated structures.

The best support, and the one on which ultimate reliance can be placed, is soundness in the natural or anatomic supports. These may be defective in original development or become defective through loss of tone, mere relaxation or partial paralysis, and the like adynamias. Warning: the utmost vigilance must be observed to avoid using immobilization for one moment after the full requirements are supplied. Otherwise the term "the curse of immobilization" becomes fully justified. Hence the need of bearing in mind the required degrees of immobilization, compensatory fixation, and temporary support.

Pathological Local Fixation due to adhesions, pareses, effects of disease or injury producing limitations, or restrictions of normal action.—Structural anomalies such as these are promising subjects for treatment by the simpler biokinetic or reconstructive measures like manipulation, corrective or mobilizing (passive) movements, and muscle reeducation to release abnormal fixation.

The conditions to be considered here are those abnormalities due to effects of disorder in structure which cause *mechanical interferences* with the

function of a part or of associated structures. These are often *accompanied by anomalies of sensation* which become relieved through movement in some of its forms or modalities—active, assisted, or passive (biokinetic remediation) also regulation of nutrition, hence is functional competence thus immensely enhanced.

While the more pronounced impairments of motor functioning are caused by severe injuries involving destructive effects on bones, joints, ligaments, fasciæ, muscle masses, skin and subdermal structures, and properly belong to the domain of surgery, there also occur many lesser ones coming within the common experience of the general practitioner.

The usual course of procedure in such exigencies is for the practical treatment to be carried out less often by the physician, who entrusts the details to lay persons, nurses, orderlies, special aides, or, when available, experts in the art of muscle reeducation. The results, when clinical authority is delegated to one not trained in medical science, far too often prove not what they should have been, and yet could have been had the surgeon or physician possessed familiarity with the main principles of the art of manipulation and muscle reeducation.

While eager to testify to the splendid work demonstrated by military surgeons in the late war, it is a fact that unfortunately few of these, here or abroad, but fewer here than in Europe, possessed either the needful knowledge or training, or even displayed interest in the resources of artistic manipulation of adhesions. Abundant occasions constantly arise here in the United States and in civil life for utilizing skill in this domain.

The present remarks are made by one who has himself always taken practical interest in muscle reeducation, in manutherapy, and who speaks from long personal experience. It has been admitted to me repeatedly by the best surgeons and those of the largest experience, that such recommendations as are now to be made should be uniformly adopted. These are to the effect that *the fate of a crippled limb or part often rests more upon the after-care,* the treatment during convalescence, and especially the skillfulness of the manipulation applied, *than upon the surgical procedures.*

Also it is conceded, and I would emphasize the point, that the imperative duty of the physician or surgeon in charge of an injured motor mechanism is to know enough of the possibilities of the case, and also of the resources of manipulation, to act at least as expert guide from start to finish of the treatment.

The manipulation of adhesions has much in common with that of other conditions of abnormal rigidity. These have been set forth in detail elsewhere under the captions, massage, manutherapy, and manipulation, and also corrective, remedial, or passive movements made upon the patient. The particular points to be borne in mind in connection with manipulations of adhesions is that *these occur much more frequently than might be suspected after slight injuries, often after diseased states, and after prolonged disuse* in almost any part of the body.

Special attention is being directed to adhesions of the abdominal and pelvic viscera. These may give no trouble, may cause serious interference with function, or may cause merely distress or vague miseries. While inflammatory conditions persist it is probable that more harm than good may be caused by manipulation. Experience is needed here, since such splendid results follow in voluntary (active) and passive (subjectively received) movements made on wound states.

When healing is slow after injuries of the limbs, and where adhesions are forming, it is of the utmost value to free these adhesions cautiously as soon as possible. By gentle lifting and pulling on the adjacent structures even while in the acute stage, it is possible so to stimulate circulation and lymph propulsion as well as nerve associations, as to expedite recovery. The best judgment is required. In my experience, however, it is most important to manipulate early and systematically. Especially is this needed where there is sluggish circulation, purulent secretion, and where extensive destruction has been caused upon bones, periosteum, ligaments, and tendons, as in neglected compound fractures or joint disease where immobilization has been protracted. Of course some pain may be given (at first, though it rapidly subsides). It is a nice diagnostic point, however, to determine from the nature of this pain and also from the tone of the tissues, how much interference to make. No harm can follow if gentleness be used. A practical point of value is to apply a broad strip of zinc oxide plaster to the parts to be lifted and pulled. This enables the fingers to grasp the skin which otherwise may slip and elude.

Some preparatory measures are often needed, as, for example, the whirling bath, or contrast bath, alternations of heat and cold.

Along the backbone, the paravertebral structures, dermal adhesions especially need release to be freed from attachments to the spinal eminences. As these "fetch away" a snap is heard accompanied by sudden pain, after which the spinal reflexes become more amenable to relief. In treating backs, whether recognizably disordered or only suspected, it is well to remember the numerous articulations, arthroses, amphiarthroses, etc., of the vertebral column. There are two distinct sets of articulations: (a) those between the bodies, the vertebral discs which form amphiarthroidal joints, and (b) those between the articular processes and arthrodial joints; also the joints of the ribs, the costotransverse articulations. These last are formed by the tubercle of the rib articulating with the anterior part of the tip of the transverse process.

Of great clinical significance and frequency are adhesions of the scalp, especially the attachments of the posterior occipital ridge and down to the base of the neck. These adhesions are connected in some intimate way with nerves, hence the causation or continuance of headache. These distresses may cease to be recognized as pain yet interfere with sleep or even digestion and circulation. Mobilizations of these areas produce most gratifying effects on sensory disturbances and on sensorifunction, *e.g.* eye, ear, nose, throat, etc.

The Resources of Hand Treatment.—Manutherapy should include the use of the hand in any and

every way promising helpfulness in relief from pain, discomfort, disability, deformation, or modifying over- and under-action or diverted or vitiated action.

Among the plus states of muscles are overtension, cramp, tonic muscle spasm, contracture, tremor, adhesion, rigidity. Among the minus states of muscles are under-tension, relaxation, impaired local tone or support, flaccidity, decrepitude, asthenia or adynamia, and the paretic effects of shock or trauma.

Among the effects of irregular combinations of over and undertension in body states are disorders in reflex arcs or circuits, structural disabilities, deformations, maladjustments, loss or impairments in power, in poise, in balance, or in equilibrium, and in diverse associated or resulting anomalies, indeed whatsoever evidences appear of a vitalized mechanism out of gear. Psychogenic anomalies must never be overlooked.

Among the systems or structures which come most readily or directly under attention, and may need controlling effects through that simple and always available agency, the hand, are:

The skin often becomes unduly adherent to the underlying structures, whereupon the subdermal spaces become relatively obliterated, and demand restoration of the advantageous conditions, the comfortable opportunities for action and reaction and interaction of blood vessels, lymph channels, and peripheral nerves.

The muscles, fasciæ, fibrous structures, aponeuroses, along with tendons and their sheaths, ligaments, and the like, which are readily disturbed, some more than others. Impairments in integrity of one structure bear such intimate relationships to those of others that not only does there ensue morphogenic change, cellular irritability or indolence, but also unique sensory alterations which deserve particularized attention, especially in order to achieve a sense of proportion in the motor and sensorimotor variants.

Here we have a group of influences exerted upon muscle tension, over- or under-tension, the release of over-tension (in hypertonus) as in cramp or tonic muscle spasm, and the reflexopathies thus indicated; also the reverse, hypotension (hypotonus), relaxation, loss of tone, paresis, also contracture, tremor, fibrillation.

To the interpretation of these neuromuscular anomalies and release from their effects, the hand is capable of making by far the largest contribution of any known agent. Perhaps in no other diagnostic and curative enterprise is a matured sense of proportion more needed or capable of offering help than here. One must have a keen kinesthesis or muscle sense, also a comprehensive motor intelligence which includes many niceties in neuromuscular make-up, to deal satisfactorily with problems of disordered motor mechanisms.

The blood vessels and lymph channels (including the heart) are peculiarly sensitive to mechanical or environmental influences, impacts, stimulation, irritation, or sedation and such effects as the hand is capable of producing are peculiarly controllable, distributable, applicable, adaptable.

Not only the vasomotor activities but fluctuations in the surface heat-generating mechanisms are thus influenced, and to such a degree as far transcends the use of most thermal agencies, so readily available and applicable. The thermogenic effects are readily activated by subdermal traction, by lifting, pulling, and separating of the dermal from the subdermal structures which not only frees the obstructed channels but induces remedial hyperemia. This stimulation of dermal reflexes, of surface heat-mechanisms acts as the full equivalent in many instances of artificial warmth or counterirritation. Should this prove inadequate, external heat can be applied by external thermogenesis, direct or through electric devices.

By artistic handling, alternating or continued (and distributed), pressure, can effects be brought to bear on vasomotor reactions on the superficial areas, but vastly more so when those areas are treated which are closely associated with spinal centers, *e.g.* the erector spinæ muscles innervated as they are by the posterior primary divisions of the spinal nerves (rami communicantes) and other "nerve points." Thus are states of vasomotor tension or relaxation or imbalance capable of being influenced or controlled plus or minus (hypertonus or hypotonus).* Hence the ebb and flow of nutrient fluids can be expedited or retarded, making for blood and lymph supply to, or release of congestion in, areas wherein such effects are desirable, *e.g.* in local anemias, hemic inadequacies or excesses, as of inflammations and suppurations, active (urgent) or sluggish (indolent or torpid). Important effects are thus exerted upon nerves in continuity, nerve centers, spinal or sympathetic (primary or subsidiary), and the interrelated or automatic. The transference of nerve impressions when in excess (pain) can be retarded, or when deficient can be expedited.

The hand is by far the most convenient, and in many respects the most safe and available means of influencing action or reaction in certain nerves or nerve centers, in particular to exalt or to depress the nervous currents in structures where these have suffered agitation, perturbation, excess passage of impulses, or upon sluggish or indolent or depressed neurones or filaments.

In particular concussion can by the hand alone (or reinforced by some such simple instrument as a bit of soft rubber and a mallet) induce far-reaching effects on the passage of spinal nerve impulses or other control through nerves in continuity and also far more dominantly upon spinal centers.

Also electrotonic influences, as Abrams teaches, are capable of being exerted or determined or controlled by the hand. The realm of diagnosis through tactile awareness, direct or contributory, has been elaborated by certain pioneer experts, the bearings and practicability of which are only now coming to be appreciated.

Many clinicians still assume that the function of manipulation is chiefly confined to producing the cruder effects of "massage," *i.e.* the squeezing, pulling, twisting, and rotating the muscle masses. The fact is manipulative remediation or adjustment or orthopedic orthokinetics), has reached a

*See article by author on "Cardiovascular Regulation" in the *Boston Medical and Surgical Journal*, October 9, 1919.

high degree of practical and scientific elaboration. These resources must now come in for the same careful, critical and experimental but open-minded attention so fully accorded to the action of drugs.

Points in Determining the Latent Power in Parts Where Movement Is Impaired, whether acute or chronic, shocked, injured, diseased, paretic or arthropathic.—To estimate the latent potentialities of an impaired limb or muscle group is not only an imperative clinical need, it is a reputable art, and also an economic enterprise. Unless the facts are determined or intelligently inferred, there will ensue blunders, delays, and loss of completeness in restoration. Also, unless the conditions, positions, etc., under which examinations are made shall be advantageous, no reliable judgment can be pronounced.

In many cripples the most serious effects and degrees of disability are attributable to discouragement or inadequate encouragement, where the primary conditions were unrecognized or neglected. Conditions in which the disabilities were apparently complete but were merely temporary, often become irremediable through neglect or wrong interpretation. Thus unless a curable malady is recognized and treated in time, the victim may become doomed to a life of local uselessness. This fate is cruel and indefensible. The information is often presented incidentally and in such technical shape as to render it difficult of access for the ordinary practitioner. A few outstanding points may serve as memoranda to aid recollection.

Among the *origins of motor disability* we may enumerate:

Acute States.—Shock, local and general; surgical shock is compounded of (*a*) psychogenic factors, commotio cerebri, fear, suspense, anxiety, phychopathy, maladjustment to terrifying situations; (*b*) somatogenic effects as of fatigue, of extremes of exertion or inaction, of exposure to cold, to heat, to dryness or wetness, of loss of sleep, of inadequate food or drink, loss of blood, pain, etc., wounds, fractures, contusions, etc.; (*c*) acute impairments in the poise of the reflex circuits and other defense reactions.

Subacute Causes of Motor Disability.—Protracted immobilization, excessive and repeated local assaults on vitality, disturbances of blood supply, local or general, in amount or in distribution, compression upon sensitive areas or structures, on blood vessels, nerves, joints, etc.

Chronic Causes of Motor Disability.—Central disorders or impairment, cerebral or spinal, the lesions may be single or multiple, along with cerebral hemorrhage, thrombosis, embolus, effusion, etc. The defense reactions, the factors of safety, may become so seriously impaired as to inhibit that measure of recuperation reasonably to be expected from estimates based on the nature and character of the causal agency in one at a fair norm of recoverability; especially remember disuse.

Adhesions between Structures designed to move freely the one over the other, e.g., aponeurotic, tendinous, ligamentous, dermal, subdermal, superficial, or deep. Contractures, asymmetries due to loss or increase of tone in a muscle group, lesions, arthritic or periarthritic, disorders of intraarticular pressure, compressions upon nerves or tubular or vital structures; the compressive effects of edemia in injuries of the cord, of suppuration, hence loss of structure, and of nutrition in associated structures; effects inducing impairments of normal nutrition or of catabolism, whether primary (as in arthritis deformans) or secondary, from long disuse and hence cell deterioration and, as a secondary cause or effect, structural anomalies in the noble organ concerned in metabolism or elaboration. A vast number of evidences of beginning arthritis deformans are found in middle-aged individuals, not at all suspected, but shown in post-mortem.

Certain other features may also occur, more or less characteristic, secondary effects which persist or fluctuate, *e.g.*, overtone (hypertonus), tonic spasm, rigidity, brawniness, tremor, or undertone (hypotonus), relaxation, and flaccidity. Metabolic disorders producing variegated causes or motor phenomena have been mentioned; these run a large gamut from goutiness to arthritis deformans. Late effects of the infections, syphilis, focal infections from teeth, tonsils, tuberculous or other bacteriogenic foci, pus pockets anywhere, exostoses, osteophytes, necroses, and probably most prolific causes of all: fecal absorption.

Among what may be called *fluctuations in features or stages or conditions common to each and every motor disability* are: variations in age, in reflex sensitiveness, responsiveness, make-up, weight, height, temperament, energy content, etc., in disposition, hopefulness, gloominess, or discouragability, resolution, fortitude, or persistency.

A most significant factor is the *degree of motor intelligence*, capability for exerting control over motor force, in velocity, in direction, in precision, and in combinations of movements (coordination), also in the degree of poise or tenderness present, in nicety of balance, of harmony, in putting the power on or off, in increasing or diminishing power transmission, carrying energy output (movement) to the finish, assuming the zero position and, graduating movement to the maximum, in describing the parabola of increments or decrements.

Also there are the contrast (motor) values, fluctuations in neuromuscular development, asymmetries in power. This can be most readily noted by comparisons with the corresponding structures on the other side. Also the length of time elapsed since the manifestations of causes.

In short, the coefficient of motor resourcefulness, of self-adaptation, of ingenuity, of eliciting the collateral or associated structures, the capabilities of graduated cooperation, the welcoming or the shirking of the day's lesson and of the total training episode.

Nerve Stretching, Joint Stretching, or Traction, to be first done by another, later voluntarily, and finally use a combination of both. To avoid performing compensatory movements during corrective and educational training is most important as making for better purposive control. Many means are available, well worth employing, of guarding against involuntary acts or local spasms which nullify the particular movements desired.

Stretching of nerves was at one time regarded

as a valuable remedial measure in overcoming the effects of chronic deterioration in nerves, especially, and associated structures, in disabling or uncomfortable or distressing conditions. Violent or forceful stretching of nerves is now seldom done, but undoubted benefit often follows gradual traction. It is entirely possible to secure similar or even better effects by passive movements and mobilizations, capable of putting disordered nerves on the stretch.

Of special importance is it to exert traction on the structures of the vertebral column in order to free restricted joints, arthroses, and amphiarthroses, thus removing pressure from the lateral processes, nerve outlets, grey rami, removing any existing stiffness or compression. Post-mortem findings often show effusions of material in bony openings which are thus obstructed.

The overaction of function in one muscle often serves as an excuse to protect another disordered muscle from action. That is, one movement induces an opposite or compensatory motion or tension in another muscle group whereby this last is protected from being stretched, *e.g.*, in bending the body the head comes up on the opposite side, the backbone curves, like an S, in compensation; hence, the long fibers are not fully stretched in the direction of motion.

The value of full control of an isolated muscle is to secure release of oventension, spasm, which later becomes contracture.*

(To be continued.)

THE NURSING PROBLEM.†

By W. D. ALSEVER, M.D.,

SYRACUSE, N. Y.

We have become so accustomed to obligatory education in our public schools that we accept the plan as a matter of course. The cost of public schools is assessed not only on the parents of the children who attend but also on other citizens, even including old bachelors and old maids. Such assessment must be reasonable or it would not continue. The object of obligatory education is to produce better citizens, and consequently to make our country safer and more comfortable to live in. This advantage is shared by all people, whether or not they have children, and consequently it is fair that all should be taxed. Similarly, the children who attend the schools, having been prepared for the battle of life through the activity of the government, are in a corresponding degree in debt to the government. This debt can be paid only through good citizenship, that is through sustained and self-sacrificing effort for the welfare of all. No one can escape such civic obligation.

A young man pays his tuition at a medical college and, after several years work, becomes a doctor of medicine. But the college meanwhile has acquired a deficit, for the tuition fees are not sufficient to maintain medical schools. Deficits are met through gifts from public spirited citizens. Such use of money is wise for it insures more and better doctors than would otherwise be the case, thus safeguarding all people including those who make the gifts. Every medical student graduates in debt to the community, even though he has paid his tuition. His debt can be paid, and is expected to be paid, through making his skilled services available to everyone and at all times. When a doctor is needed it is manifestly his duty either to go or send. The only satisfactory excuse is physical inability. I am happy to say that, as a rule, doctors perform this civic duty.

A young woman enters a nurses' training school. She pays no tuition; on the contrary she receives board, lodging and a small salary. However, she contributes her labor in greater degree than is needed for her education and so, for all practical purposes, she pays tuition. That she does not pay the cost of her education may be inferred from the fact that hospitals, like medical colleges, have regular annual deficits which are made up by the generous well-to-do. Consequently all nurses graduate in debt to the community. They rest under the moral obligation to nurse the sick to the extent of their ability. Were it not so, general public support of nurses' training schools would be unjustifiable. There is a public demand for nursing as well as medical care of the sick, and public support of hospitals grows out of it. If hospitals, doctors, and nurses should fail to give the public reasonable care in sickness, then public support of them would eventually be withdrawn. The public demands service and is certain to get it. That person who enters medicine or nursing for the sole purpose of making money has adopted the wrong course and is not honest in accepting the education offered.

We all feel that the best possible nursing care is desirable, and we feel it the more keenly when we ourselves or those near to us are the patients. At present a fully trained nurse receives $5 or more per day and board. Under the 12-hour duty system it often happens that one nurse is of comparatively little value, and we choose between two nurses or none. If the patient is in a hospital, the hospital bill must be added and, usually, the doctor's bill as well. It is generally known that doctors' bills vary according to the standing of the doctor and the ability of the patient to pay. Hospital bills vary according to the rooms chosen. Nurses' fees however are fixed. There is much to be said in favor of uniformity of nurses' fees and it has the backing of established custom. For the purposes of this discussion, at least, uniformity of nurses' fees may be accepted as proper.

It will be seen that sickness, if properly cared for, is expensive, yet within the easy reach of the well-to-do. Through our public charities good care is also within the easy reach of the very poor. For the great bulk of the people, who are self-supporting and who resent charity, the proper care of sickness is a heavy burden. Yet this middle class comprises about 90 per cent of the people, it is the bulwark of the nation, the great men of to-day have come from it, and its children will furnish the great men of to-morrow. It must not be pauperized nor humiliated. Five dollars per day is an ordinary wage for a head of a family. The man who nets

*See "Treatment of Sciatica," giving experiences on the author's own person, by A. C. Wittenrod, in Ned. Tidjdschrift v. Geneeskunde, March 12, 1921. Abstract *J. A. M. A.*, June 11, 1921, p. 1720.

†Presidential address delivered before the Fifth District Branch of the Medical Society of the State of New York.

$10 per day is doing very well indeed. To ask such a man to spend five or ten dollars per day and board for one or two nurses, in addition to the other expenses of sickness, is to ask something which is clearly out of proportion to his income. This does not mean necessarily that graduate nurses charge more than they are worth, but it does mean that under the present system trained nurses are not available for the mass of the community.

There are other minor phases of the nursing problem which may properly be mentioned. At present there are not enough nurses to supply the need, even if twelve hour duty was abandoned. Twelve hour duty has laid a heavy burden on the community without lightening the burden of the nurses in proportion. Practically every mother does twenty-four hour duty. As a routine procedure twelve-hour duty for nurses is wrong. It should be reserved for the more burdensome cases only. The custom of employing trained nurses for wealthy semi-invalids is unfair if these nurses are needed by sick people. In a large percentage of cases proper treatment depends quite as much on a trained housekeeper as on a trained nurse. Commonly graduate nurses do no housework and consequently they miss many opportunities for relieving the sick. The mental state of both patient and family is an important and much neglected factor in the treatment of disease. The sick housewife is disturbed and restless when she knows the house is running badly, and she is all the more distressed when she realizes that the household cares have become heavier through the presence of a guest—the nurse. If the patient is husband or child, the housewife's cares and duties are greatly increased and help of any sort is thoroughly appreciated. It is difficult to explain the ethics of a situation which overburdens the mother with housework and permits the nurse to sit in a comfortable chair doing fancy work. Although I personally know that such situations have occurred, yet I also know they are rare. I can say, with much pleasure, that I have often known graduate nurses to make themselves useful in all possible ways, after the patient had been cared for. Nurses who began training in their teens and who have done nothing but nursing since, naturally cannot be expert housekeepers and we must not expect too much of them.

A recent development which makes the solution of the nursing problem more difficult is the choosing of cases by nurses. It is proper for some nurses to limit their work to special fields in order to increase their efficiency, for example operative cases, obstetrics, quarantinable diseases, etc.; but the majority of nurses should hold themselves in readiness to accept calls as they come. It is their civic duty—should they fail in it, the nursing profession must descend from the high place it has occupied. Every doctor and many families have known of nurses refusing calls because the case was out of town, because the diagnosis was unsatisfactory, because the disease was mildly contagious although not quarantinable, because there were no servants in the house, because the doctor or the family were not agreeable, because the case was difficult, because it was not in a hospital, because only one nurse could be afforded, or because it was holiday time. These excuses are mentioned with chagrin and shame. However, the spirit of human kindness is so strong in all people that, in my opinion, these abuses will be corrected as soon as nurses understand that public opinion condemns them.

Many of the phases of the nursing problem do not, in my opinion, call for criticism of the nurses themselves. They rather are part of the trend of the times and have involved nurses no more than other groups of workers. Rome fell after her people were surfeited with power and wealth. The United States has grown so strong and rich that we are seeking ease and pleasure, forgetting our sturdy ancestors who vivified the doctrine that the greatest health, wealth and happiness comes through work and that all work is honorable. The most conspicuous exponents of the new order are the labor unions who use force to the limit to raise wages and shorten hours of work. Their doctrines of the closed shop and restriction of the numbers of apprentices are pernicious and unfair, and must be overcome or we all, including the unions, will suffer. However much we may evade it temporarily, yet in the end the law of supply and demand controls. At present there is a demand for more extensive and less expensive nursing among middle class people and undoubtedly this demand will somehow be supplied.

The question naturally arises "who should solve this problem?" It really is everybody's problem, but everybody's problem is nobody's problem. Practically all public health problems have been solved by doctors, they being the ones best trained for the work. They are proper judges of efficiency of nursing in cases under their care, and they may well qualify as advisers in the nursing problem. Perhaps nurses themselves should take the lead in this matter for they already know more about it than do any other group of people. It is another phase of their civic duty. There is now a strong tendency to regulate the practice of nursing by law. The more the law restricts the freedom of people in general to qualify as nurses, the greater the obligation on those who do qualify to see that the community is well nursed.

There are at least three possible plans for improvement. First, the salaries of graduate nurses might be lowered. This is not to be advised for it would probably be unfair to the nurses, it would no doubt diminish the number of nurses in training, and it might eventually diminish the number or quality of those highly trained women needed for hospital superintendents and teachers.

Second, the field for graduate nurses might be limited to institutional and other salaried positions and to care of the well-to-do, thus leaving a large field for women who are less highly trained nurses but better housekeepers and who can afford to work for less money. Various attempts have been made to train such nurses, but, as yet, no plan has met with universal favor. New York State and California now license so-called "Registered Nurses" and "Trained Attendants." They continue to permit the care of the sick by other people regardless of their training and experience, that is by those who are known as "experienced" or "practical" nurses. "Registered Nurses" are those who have completed courses in training schools approved by the State and have conformed to the few rules required for license. Practically they comprise those

who were formerly known as "graduate" or "trained" nurses. "Trained Attendants" must have completed a short course (6-12 months) in a hospital approved by the State and conformed to the rules required for license. It is expected that hospitals of small capacity, hospitals for chronic cases, for the insane, for the tuberculous, etc., and possibly the larger general hospitals, will establish approved courses. These new laws have been in effect too short a time to know how great will be the supply of "Trained Attendants," but as yet hospitals have shown little interest in this type of nurse. Being deprived by law of the designation "nurse," "Trained Attendants" will probably be somewhat handicapped in prestige. In the English language from time immemorial the word "nurse" has meant any one who cared for the sick and probably its meaning cannot be changed by law. If custom continues to give the meaning to words, then "Trained Attendants" will be known popularly as nurses, or few people will become "Trained Attendants." In any event it is highly desirable to develop a large group of nurses who have had short hospital experience. The practical problem is how to get many people to aspire to be "Trained Attendants" and how to get hospitals to train them. Whether the advantages of a legal classification of nurses are greater than the burden and expense of registration is yet to be determined. Undoubtedly we always will have with us the non-descript group known as "practical" nurses and many such nurses continue to be of inestimable value. Their housewifely skill and their willingness to do whatever may be needed to overcome disease are assets which loom large.

Some attempts have been made to train nurses by instruction outside of hospitals. The National Training School for Certified Nurses at Albany offers a six months' course and the Chautauqua School of Nursing gives a course by mail. Following the influenza epidemic the Chicago Training School for Home and Public Health Nursing was organized. It gives a two months' course consisting of lectures and demonstrations. In two years it has graduated 4,000 women, averaging over 40 years of age, half of them married or widowed and most of them experienced housekeepers. However great the defects of such schools may be, their graduates are better qualified for nursing than was the case before they carried on their studies. It is beyond question that a capable woman can become a good nurse after a few months' training, for many such women have demonstrated in actual practice that they *are* efficient. Charging usually twenty or twenty-five dollars a week and accepting twenty-four hour duty, they are available to many families who find it difficult to maintain trained nurses. Graduates of these schools who do not practice nursing are so useful in their own homes that nurses from the outside are seldom needed. Evidenty the community is helped by these schools and, until better sources for moderate priced nurses are operating, such schools should be continued. Graduate nurses need not fear competition for there is plenty of work for all.

It has been suggested that the need of most homes for nurses can be diminished by giving courses in nursing in the public schools, just as cooking and sewing are taught. There is much to be said in favor of this plan. Surely it is just as reasonable to teach school girls the care of the sick as to teach them the other house-wifely arts. Semi-public institutions, such as the Red Cross, have given courses in practical nursing. Considerable benefit and no harm has resulted.

An attempt is being made to increase the number of pupil nurses in training schools through shortening the course to two years or thereabouts. Probably this can be done without lowering the efficiency of the graduates, but the cost of their education will grow. Increasing the numbers of graduate nurses will help to solve the nursing problem, but unless they work for lower wages the mass of the people will not be benefited. Lowering the pay or shortening the training of graduate nurses would be inadvisable if loss in quality should result, for difficult cases will continue to demand all possible skill and the maximum of training and native ability is needed for superintendents and teachers.

A third possible plan for relief is the use of paid, fully trained, visiting nurses. During a daily visit a nurse can give special treatments, bathe and otherwise care for the patient, take pulse and temperature, and advise regarding diet, ventilation, care of excreta and general hygienic questions. Much valuable public health information can be diffused through neighborhoods by such nurses. Their visits are especially valuable to families who cannot afford resident nurses or who live in apartments so small that another person cannot be housed. In order that the work can be done for moderate prices, the patients must live near together. That is to say visiting nurses are practicable in densely populated communities only. They can never supply the need if distances are great or if continuous care is needed.

All these plans for relief are imperfect, all have their advantages. They give abundant material for discussion. The nursing problem is vital just now and demands careful consideration by all people, but particularly by nurses and doctors. In studying it one must remember that the fundamental motive in nursing is to relieve suffering—this includes not only the actual care of the patient, but also the relief of the anxious and overburdened family. A true nurse must have some of the spirit of a crusader or a missionary. She must conduct herself so that other people will want to work with her; so the family will be glad she came and sorry she went away. Kindness of heart, secretiveness, good breeding and general education are important. We all need to remember that the greatest pleasure and comfort in life come not through money, but through work well done. It happens that the nurses' opportunity for service is notably great.

The question naturally arises what can we, as doctors, do to help solve the nursing problem, and the answer is not easy. Public sentiment has not crystallized around any of the proposed plans for relief. Our civic obligations lead us to investigate the nursing situation just as surely as they lead us to study other public health questions. Our moral responsibility is fixed and unavoidable. We are just as much responsible to the public for the nursing care we accept as we are for the quality of the

drugs we administer or for the sterility of our hands when operating. The question is not "ought we to do something," but "what can we do?" As with other unanswered public questions one thing of value which every one can do is to talk, and everlastingly to talk. Out of the meeting of many minds, which is the sure result of general public interest, will come the answer to this question. You and I can help bring out the best ideas through conversations with our acquaintances, particularly with nurses, and through discussions at formal meetings. Only little readjustment will be required to develop nurses according to any of the proposed plans. The problem resolves itself into agreeing on the best method of supplying moderate-priced nursing.

When it becomes generally known that the way is open for the training of reasonably satisfactory nurses in short, inexpensive courses, there will then be no difficulty about candidates for the returns in self respect and money will be attractive.

Hospitals hold their pupil nurses for several years in order to train them in various technical details and in order to take advantage of their services. Just as special preparation is required for public health nursing, so it is needed for private family nursing. Hospital training makes a nurse competent to establish an operating room in a house, but does not prepare her to care for ordinary sickness without upsetting a home. Fifty years ago girls were taught housekeeping in their own homes and nurses were competent housekeepers first. Such is not the case now. Florence Nightingale lifted the nursing profession to the highest moral plane. Relief of suffering was her sole object. When she went to the military hospital at Scutari her first and most useful work was in making the hospital wards clean and free from vermin, the patients' bodies and their beds clean, and in serving good food. This work, done in considerable part by her own hands and in spite of the opposition of the military authorities, greatly increased the percentage of men returned to duty. It was tremendously valuable nursing, but it was housekeeping.

Let us do what we can to develop a class of nurses who know a little of the science and much of the art of nursing, who are ready to do whatever may be needed to make the sick well, who think less about the infectiousness of disease and more about the contagiousness of the Golden Rule, who are like mothers or sisters to their patients, who are true disciples of Florence Nightingale.

TUBERCULOSIS A DISEASE OF MALNUTRITION.

By EDWARD H. CLEVELAND, A.M., M.D.,

ROCHESTER, N. Y.,

FORMERLY ASSISTANT SUPERINTENDENT, WESTERN MAINE SANATORIUM.

It may as well be acknowledged, without further delay in a matter so important, that the disease known as tuberculosis, including the pulmonary form of it, is due in the final analysis to the failure of nutrition. In other words, consumption is the result of starvation, the evidence of a starved condition. Those who are unfortunate enough to be born into the world with deficient assimilative powers must naturally become the subjects of malnutrition in one form or another. Granted that no two persons are precisely alike in this particular, sooner or later the individual inability to get the good of one's food, day after day, will result in a breaking down of health. This breaking down may be sudden or gradual, according to circumstances. Disease of the lungs should direct attention at once to some congenital weakness of the alimentary canal, since the lungs are, after all, simply an appendix or annex to the digestive organs of the human body. Inefficiency of the digestive function produces an impoverishment of the blood and tissues, varying in degree with existing conditions, and the lungs, being overworked and under-nourished, become susceptible to the toxins of tuberculosis. Other localization of the disease will readily suggest a similar etiology.

No one questions the importance of contributory causes, such for example as the depreciation of vitality through illness of some serious sort, or as the result of physical shock or mental strain, or of an acute emotional disturbance. External and internal injury have their legitimate share in the development of disease. Sorrow after bereavement, loneliness in separation, injudicious habits of life, all come in for a share in the ultimate responsibility for the depressed and depleted condition. Other elements may easily be added to this brief list. But in the long run it is the weakened state of the physique in general, due primarily to an inability to replace the results of the ordinary wear and tear of daily activity, on which the burden of responsibility is to be laid. "I was all run down" is the common explanation. Now, we submit that the planting of the seed is not so important as the preparation of the soil for it. If the seed is to be fertilized, there must first be the furnishing of conditions favorable to its due development. This is especially true in the matter under consideration, because the seed is quite sure to be pretty widely distributed anyway, whether or not the soil, which in this instance is the human system, has been made ready to give that seed a hearty welcome.

It is claimed by experts, apparently with good reason, that infection with the Koch bacillus is practically a universal experience, during the first ten or twelve years of human existence. Careful records of many scientific autopsies seem to bear out this view. The strong constitutions among us ordinarily are able to overcome the injurious effects of this early infection, before these effects have gone far enough to do serious damage. Nature rises to the emergency, and successfully combats the insidious enemy. In a large proportion of cases, an immunity to future attack is believed to be conferred, similar to that of vaccination. The weak constitutions, on the other hand, are by nature predisposed to develop disease when conditions arise which favor such development. They cannot easily throw off infection.

At this point in our present discussion, the paramount importance of strictly hygienic living, and more especially the necessity of establishing and maintaining good nutrition as the habit of one's life, becomes unmistakably apparent. No matter what the other causes of physical depletion or men-

tal depression that may exist, in any instance, a steady habit of good nutrition will go further than any other counteracting influence to affect or overcome a weakened resistance. Even although no untoward circumstances of other sorts come into one's life, a failure to provide proper and regular nourishment will of itself lay open the system to hostile attacks of any and every variety. It is fair to conclude, therefore, that the peril from the presence of the tubercle bacillus, encroaching on every hand, has been somewhat overemphasized, and the fortifying effects of suitable and sufficient food and drink have been underestimated. Indeed, everything must be subordinated to this simple but essential consideration, if justice is to be done to the situation in which we find ourselves.

It is not too much to say that a comparatively poor physical endowment, under the constant support of a habitually adequate assimilation of nourishment, coupled with reasonable proportions of outdoor air and exercise and rest, and a wise observance of the rules of health, may count upon the avoidance of many varieties of infection, and, where these cannot be avoided, may expect to undergo only light attacks of disease, readily and safely endured. Again, a more vigorous constitution, poorly nourished, by reason of carelessness or inattention, or owing to the pressure of exceptional privation, will find itself subjected to many passing illnesses, *against which the system has not been sufficiently fortified by good nutrition*, and will hardly escape certain unfavorable after-effects. These naturally will contribute to the further reduction of that degree of original resistance which characterizes a physique well-endowed by nature.

With these points kept clearly in mind, one may boldly state that we all dwell daily in the midst of infections, receiving unconsciously to ourselves or others the potential germs of various diseases, in the course of infancy, childhood and adolescence. The balance of probability, to say the least, is in favor of those individuals and families who have been well-nourished from the start. Some wise man said that in order to secure a satisfactory education, in any given case, we must begin with the child's grandmother. This great question of the personal possession of health and expectation of life takes us back at least two generations. It is not enough to provide hot lunches for hungry school-children, in city or country. All the after-care of our boys and girls will prove of little avail to make up for scanty or improper or poorly-judged nutrition during the prenatal existence of the individual. We cannot tell how the bones grow in the unborn, perhaps, but we know, or ought to know, that if the mother is lime-starved during that crucial period, her child, *and by natural sequence all its future offspring*, must suffer from inadequate, not to say stunted, physical and mental endowment. Exceptions, if any, only serve to prove the rule.

To counteract the tendency to tuberculosis is of infinitely greater importance than to take the most scientific care possible of patients already discovered, however early in their lives, to be in the clutches of this desperate foe. If people are not well-nourished, and their blood clean and untainted, how can they in the nature of things expect or hope to bring into the world strong and healthy children? Can the stream rise higher than its source? Nature may, and often does, make a show of abounding health in children of weak parents, owing to the wonderful impulse of vitality which commonly belongs to early years. But some day the fact of the depreciated stock will appear. How often one sees bouncing babies, blooming girls, and husky-looking boys and young men, begin to grow pale and thin and weak, unaccountably as we often say, for no apparent reason except that their start in life was under the handicap of physical weakness, most commonly due to a lack of proper assimilation of nourishment or careless habits of life on the part of one or both parents. These children simply are not well-born. Too many of our best and most useful men and women die before their time. Human life is shortened, chiefly, because human beings are not enabled to enjoy proper and sustaining nourishment. We are jerry-builders of the house of life, and at the first real shock it tumbles in ruin about us.

Our plea, then, is for an intelligent diet for everybody, but especially for those who hope to have children and grandchildren, if they wish to see their offspring vigorous and strong. We plead for every kind of hygienic living, even in things permissible, for the sake of those innocent and confiding little ones to whom we can impart nothing more desirable or essential than sound health, *mens sana in corpore sano*. We plead for soap and water, for cleanliness of body and mind, that our children, dearer to us than life, be not tainted or weakened by our neglect or carelessness. We glorify the homely virtues of self-control and self-denial and sobriety, lest the stock we hold in trust for future generations should suffer degeneracy through any fault of ours.

Tuberculosis is a disease of malnutrition. We insist, we cry aloud, we publish it from the housetops as our message of warning to the men and women of today, that there is no such thing prospective or possible as the control or the conquering of tuberculosis, unless and until we are all willing and determined to see to it that life-long habits of hygiene, and of the adequate assimilation of proper nourishment, become a religious duty in every household and family. If we will not live rightly, and eat and drink wisely, our children must pay the penalty for our shortcomings. It is not so much a question of what we shall eat or not eat, for oftentimes what is one man's meat may prove another man's poison. But each of us must decide for himself and for herself, that whatever goes down his or her throat in the way of food or drink shall be constructive, and not destructive, shall help and not hinder the wholesome processes of nutrition and of elimination. Experience is a good school, few will learn in any other, and some hardly then. Forewarned is forearmed, and an ounce of prevention is worth tons of medicine. Establish good assimilation, secretion, excretion and elimination, at the outset of life, or as near that as possible, and strive diligently and unceasingly to maintain them, and you need not fear either the onset or the sequel of any infection.

Since, by all accounts, from those who have made the most thorough study of this problem, we can-

not be sure of avoiding the personal uninvited visits of the tubercle bacillus, whose name is legion, even under the most strenuous precautions, let us, for our own sakes and our children's sakes, live as reasonable men and women should live, eat and drink as intelligent men and women should eat and drink, who prefer to become and to remain, if not wholly immune at least superior to the poisons which good nutrition and hygienic habits of life alone can suffice to render harmless, alone suffice to overcome. "Had I known beforehand," said an ex-patient to the physician, "what I learned in one year at the sanatorium, about taking care of my health, I don't believe it would have been necessary for me ever to go there." In his chapter on "Symptoms," Dr. Francine of Henry Phipps Institute says, "Nothing can be accomplished in the treatment of tuberculosis until the gastrointestinal function is restored." May we not go a step further and say, "Nothing can be accomplished looking toward the eradication of tuberculosis, until the gastrointestinal function of every man, woman and child has received the full measure of respect and protection to which it is entitled?"

Due weight must be given to the statement of the late Dr. Osler, quoted from his "Historical Sketch": "Of course we have to recognize the very widespread prevalence of the infection. Only a comparatively few persons reach the age of fifty without a focus somewhere of tuberculosis. Upon the personal hygiene of the individual depends largely whether or not he becomes consumptive. All debilitating circumstances render the body less able to keep the invader in check." For example, there is no longer any question as to the injurious effects of the moderate habitual use of alcoholic beverages and of tobacco in any form. That these poisonous substances tend powerfully to reduce resistance, in every case, is a scientific fact that should be more generally recognized. Advertisements do not mention this fact. Their destructive influence upon the heart and the nervous system, as well as upon the digestive organs, coupled with irregular and abnormal habits in other respects, directly contributes to the causation of tuberculosis, and to its development after the actual process of the disease has become definitely established. It is notorious, indeed, that nothing more seriously interferes with the progress of many patients toward relative recovery and restoration to usefulness, than a childish adherence to habits of which it may be said that they not only depress the bodily condition but enervate the mind.

Two steps in advance we all must hope for, and do what we can to encourage. First, physicians in general practice, who are called upon to examine patients in whom incipient tuberculosis is suspected, should no longer be excused for telling such patients that it is only a bronchial condition. It is a pity that people generally are left in such ignorance as to believe this, when the existence of tuberculous infection is a well-nigh universal experience. No sensible person need allow himself to become the victim of undue apprehensiveness in regard to it. If our daily lives were wisely ordered, so as to enable us all to avoid or resist the infection, then actual tuberculous disease would become comparatively rare within a generation or two. More people die of ignorance and carelessness than from any other cause. If our children were taught in school what patients go to the sanatorium to learn, there would be less need for sanatoria. Secondly, a slight hemorrhage is not necessarily to be regarded as a vital or even as a dangerous symptom. Dr. Lord says, "In the majority of cases this symptom appears to influence the outlook little if at all." The same authority indicates that a hemorrhage is less menacing than an effusion of blood in the lungs when not expelled therefrom. Hence, a slight actual hemorrhage may be a benefit, since it is one of Nature's own measures for relief. Strong men have had in their youth an attack of this sort, and yet these same men have afterward lived in health and activity to a good old age, in part no doubt because they thus learned caution.

THE TRAINING AND PROPER RECOGNITION OF THE PHYSIOTHERAPY AIDES.

By J. F KRASNYE, M.D.,

LOWELL, MASS.

FORMERLY ASSISTANT PHYSICIAN, BOSTON PSYCHOPATHIC HOSPITAL, BOSTON, MASS.; FORMERLY ASSOCIATE PHYSICIAN, RING SANATORIUM AND ARLINGTON HEALTH RESORT, ARLINGTON, MASS.; FORMERLY SUPERINTENDENT, PINEWOOD SANATORIUM, ARLINGTON HEIGHTS, MASS.; FORMERLY CHIEF, NEUROPSYCHIATRIC SERVICE, BASE HOSPITAL, CAMP DEVENS, MASS.; CONSULTING NEURO-PSYCHIATRIST AND DIRECTOR, MASSACHUSETTS COLLEGE OF PHYSIOTHERAPY; PROFESSOR OF PSYCHIATRY, UNIVERSITY OF MASSACHUSETTS, SCHOOL OF MEDICINE, CAMBRIDGE, MASS.

PHYSIOTHERAPY has heretofore met with more or less disfavor among the members of the medical profession because of the lack of thorough scientific courses in physiotherapy in medical colleges and schools of nursing and the low standards of thoroughness and scientific exactitudes insisted upon.

The value of physiotherapy as an important and indispensable adjunct to medicine and surgery is now recognized and is being rapidly taken up by the medical profession. This has been visibly demonstrated by the installation of Departments of Physiotherapy in many of the Allied hospitals during the World War. The United States Government established a Department of Physiotherapy in connection with the Surgeon-General's Office at Washington, thus giving Government recognition to physiotherapy which was the only form of "drugless therapy" that received such recognition. The results obtained from the application of physiotherapeutic measures among the wounded soldiers in our reconstruction hospitals have been most gratifying and there is no doubt that in all the Government hospitals of the future the Department of Physiotherapy will be one of the foremost. In fact, so well known have these treatments now become that nearly all up-to-date hospitals and sanatoria have installed departments of this character under the care of competent and skilled physiotherapists.

Physiotherapy is a "specialty," and therefore requires "special training." As the demand for this form of therapy is now steadily increasing, it becomes absolutely necessary that there should be highly skilled and thoroughly trained men and women to meet this need of the profession. This requires the teaching of a college solely devoted to this line of work with all its clinical facilities and

with competent instructors to demonstrate and teach the various methods upon the living subjects or patients in the clinics. The subject of physiotherapy should be included in the curricula of all medical colleges, so that the graduate M. D. could intelligently supervise and prescribe this form of treatment. It should be one of the required subjects of every nurses' training school, thus enabling the graduate nurse to become a skilled physiotherapist.

Physiotherapy includes principally hydrotherapy, electrotherapy, massotherapy, vibrotherapy, phototherapy, thermaerotherapy, kinesotherapy, etc., thereby embracing any form of treatment that is administered by manual or mechanical means, which tends to restore the normal physiological function of the body. In order to do this it is necessary to have a thorough understanding of anatomy, physiology, pathology and hygiene.

Due to the remarkable development of physiotherapy it is practically impossible to man these departments with graduate medical personnel. The reasons for this are obvious:

1. The inexcusable lack of teaching of physiotherapy in medical and nursing schools.

2. Most young physicians prefer other lines for the development of their special faculties. Only a small number deliberately select physiotherapy as a permanent career. The same may be said about the nurses.

3. The general practitioner does not attain expert physiotherapeutic acquirements, as he seldom feels that he has the time to spare for either the study or the practice of physiotherapy.

4. The graduate or registered trained nurse is incompetent to give physiotherapeutic treatment as the subject was not taught or demonstrated to her in her class or hospital work.

We are therefore confronted with the following situation:

1. A rapidly growing appreciation on the part of the medical profession of the need for help or assistants in physiotherapy.

2. The establishment of more and more departments of physiotherapy in health resorts, sanatoria and hospitals which are taking part in the standardization plan now under way.

3. The development of private physiotherapy departments in the offices of individuals or groups of individuals practicing medicine and surgery or specialists in neurology, psychiatry and orthopedics. All this has created a demand for workers which the medical colleges and nurses' training schools alone could hardly supply, even were their graduates willing to enter upon this career.

The medical directors of physiotherapy departments have been helped materially by the advent of the "Physiotherapy Aide." Who and what is a "Physiotherapy Aide"? He or she, more commonly the latter, is a faithful ally and helper to the director of physiotherapy or his assistants. It is sufficient to say that at the present time there is a group of women (and an occasional man) who have seriously entered upon the career of physiotherapeutic work. Their preliminary training has been as variegated as that of the medical graduate of the pre-standard days of medical school requirements. Some have just "picked up" the technique around some doctor's office, sanatorium, hospital or health resort, and have little or no education and possibly have begun their medical work in the humble capacity of office attendant. Others have a high school education and have then secured a position as a helper. More recently a number of college-bred women have prepared themselves for the work by taking up science and physical culture courses. In short, just as the demand has grown, so has the supply been made fairly adequate by the entry into our ranks of these women workers and, as a better appreciation of their labors has been manifested, so a better prepared class are entering. The reliability of the graduate in physiotherapy is in direct proportion to his or her general education, training and clinical experience, just as is the case with any other special workers in medicine. I have known physiotherapists who have gone the length and breadth of the land, surveying and watching the work at various sanatoria and hospitals, taking special courses with various specialists, returning much improved in technique, just as is done by all workers in medicine who wish to keep abreast of the times. The well trained, properly educated, honest and reliable physiotherapy aide is of inestimable help to us and we cannot get along without her because she is fully able to give physiotherapy treatments as required by physicians in their every day practice.

Owing to the great demand for physiotherapy aides or graduates in physiotherapy, and the scarcity of medical and nursing talent to perform the work, we must look elsewhere for help. That "elsewhere" is the graduate physiotherapy group. Since their work is highly satisfactory it behooves us as medical men, to whom these people come for their employment, to lay down certain standards both for preliminary training, theoretical and clinical physiotherapeutic education, which we consider fitting requirements for entrance upon serious labor of this kind.

Medical examining boards reinforced by the remarkable self-purifying process undertaken in the past twenty years by the medical schools, urged and helped by the Counsel on Medical Education of the American Medical Association, have brought order out of chaos in American medicine and are producing a medical product called a "physician," who is really properly trained to pursue his calling with the minimum of danger to the individual citizen who from time to time is designated the "patient." The medical school problems are therefore well nigh solved. The same may be said of the training schools for nurses and their product the "nurse." However, this is not so with the physiotherapy "aide." We have no organized schools for their training, neither have we State medical examining boards for physiotherapy aides or graduates in physiotherapy, nor does there exist, so far as I can ascertain, any board, committee or association which passes upon the qualifications of these physiotherapy aides. During the late war their services were much sought after for government work and were eminently satisfactory according to the army authorities. The United States Public Health Service also uses the services of physiotherapy aides.

If you will note the number of advertisements

each week in the columns of the leading journals asking for physiotherapy aides or graduates in physiotherapy you will gain some idea of the insistent demand for them. If you will also realize how difficult it is to secure the services of an "aide" at a distance, who has by virtue of the present haphazard system, no diploma or certificate, except letters of recommendation from past employers, you will likewise appreciate the difficulty for a medical director of physiotherapy to engage these people without a trial, which at times is very expensive and impossible. How much better would it be were the prospective aides able to say, "I am a graduate in physiotherapy from this or that college and hold a certificate of ability from this or that medical board," thus simplifying the process of employment and of the appraisement ability considerably.

Recommendations. — 1. The establishment of schools, under proper direction, for the training of physiotherapy "aides".

2. The recognition of graduates in physiotherapy by some kind of board, or possibly some volunteer examinations conducted by a representative medical director of physiotherapy in each one of our metropolitan cities, with authority to pass upon the qualifications of applicants to practise physiotherapy and give a certificate of merit to those who deserve it.

3. The organization by the graduates in physiotherapy, themselves, of an association having for its objects the betterment of their professional status, the purging of incompetent aides from their midst, and the spreading of propaganda throughout the land among organizations and colleges for the purpose of enlisting the interest of women and men in this work, and encouraging the entrance of properly trained persons into physiotherapy schools, thereby, giving us competent graduates in physiotherapy called "aides."

29 Bridge Street.

AN IMPORTANT SIGN IN THE DIAGNOSIS OF BEGINNING PULMONARY TUBERCULOSIS.

By W. FOREST DUTTON, M.D.,

TULSA, OKLA.

Laënnec, in 1819, gave to the world his work "de l'auscultation médiate ou traité du prognostic des maladies des poumons et du cœur, établi principalement à l'aide de ce nouveau moyen d'exploration." It would seem that this was the first work to deal at length on auscultation. The immortal services of Laënnec to medicine marked the beginning of a new era in the diagnosis of internal diseases.

Later in 1841, Henri L. Roget, in conjunction with Barth, published a "Traité pratique de l'auscultation."

In 1833, Doctor James Jackson, Jr., of Boston, while a student in Paris, communicated to the Société Médicale d'Observation a paper on the prolongation of the expiratory sound as an important sign of the early stage of phthisis. This sign is now universally recognized. Among some of our more recent teachers of physical diagnosis may be mentioned Alfred L. Loomis and Austin Flint, New York; J. M. Da Costa, Jr., Philadelphia; R. C. Cabot, Boston.

The interpretation and conception of auscultatory phenomena remains essentially the same as in the days of Laënnec and Skoda. Laënnec maintained that these were pathognomonic signs for definite morbid conditions and formed empirical categories of sound. Skoda endeavored to place his findings upon a scientific basis, hence, his memorable physical rules founded on principles of acoustics.

The works of to-day on physical diagnosis do not offer much on auscultation that has not been investigated by the cultivators of physical diagnosis of the nineteenth century.

During the course of time innumerable modifications and combinations of Laënnec's instrument have been made, but few are of value. In diseases of the chest the stethoscope proves of most value in stout persons or in cases where the examiner has defective hearing.

When the chest is not excessively fat or muscles too well developed, auscultation should be practised by the ear alone. A chest emaciated or covered with hair cannot be successfully auscultated with any instrument.

The value of auscultation in the early diagnosis of pulmonary tuberculosis is questioned by many writers. This is so prevalent that I am prompted to use the language of Doctor Oliver Wendell Holmes who, in discussing the question, "How far are the external means of exploring the condition of the internal organs to be considered useful and important in medical practice" said: "At the present day it is well known that some practitioners of certain merit, and particularly some who pride themselves on strong sense and intuitive sagacity, habitually neglect and depreciate the value of physical signs, even of thoracic disease."

Is there any valid reason why pulmonary tuberculosis should be called "chronic," or perhaps, better to say, become chronic? It is my experience based upon clinical evidence that 90 per cent. of the cases of pulmonary tuberculosis can be detected before the usual stereotyped signs and symptoms as crepitant râles, percussion notes, narrowing of apical resonance, cough, anemia, palpitation, or slight fever, become recognizable. Why the use of the words initial, incipient, or developmental period, to express a condition not fully described by writers under these captions.

The signs and symptoms usually attributed to *phthisis incipiens* are certainly not present at a stage that pulmonary tuberculosis should be recognized!

The writer of to-day, for convenience, distinguishes three stages or degrees of pulmonary tuberculosis: (1) the initial, incipient, or developmental period; (2) the stage of well-established infiltration; and (3) the terminal stages with signs of cavity formation. In referring to patients, they are classed as mild cases, cases of medium severity, and advanced cases.

The mild cases are usually described as those in which the disease is limited to a small area in one lobe. This area is the apex and does not extend below the clavicle or the spine of the scapula. There may or may not exist fine râles that are non-con-

sonating. The medium severe cases are those extending beyond the limits of the mild but not as far as the advanced case. The advanced cases involve one whole lobe or several lobes, with cavity formation. The stage of pulmonary tuberculosis that is of prime importance and about which so little is apparently known is the initial stage. The physical signs attributed by most writers to phthisis incipiens are as follows: Râles heard at one apex in front and rear which may be either fine crepitant râles, or bronchi. The enfeebled, or roughened respiratory murmurs, with prolonged expiratory sound, cog-wheel, or indefinite breathing may be in evidence. The percussion note may be normal, or there may be slight deviation above or below normal pitch. On inspection, a slight lagging of movement of affected side. Dry cough, with or without sputum, is a common symptom. Tubercle bacilli may be demonstrable in the sputum. Occasionally hemoptysis takes place. Anemia, dyspepsia, fever and pleurisy are noticeable in many cases.

These signs and symptoms are not found in more than ten per cent. of the cases of beginning pulmonary tuberculosis. The ninety per cent. of the cases of actual beginning pulmonary tuberculosis are not diagnosed by these signs and symptoms. It is to this class of patients this paper is devoted.

In the years from 1903 to 1913, the writer examined some 20,000 persons. These people represented various walks of life from laborers in the mills to bankers and presidents of large corporations.

A condition not previously observed by me was found, from time to time, in the examination of the lungs. It was not a sound described in texts and was for awhile puzzling.

After a number of years of close observation of each patient the sound was found to exist in only one condition, *i.e.* pulmonary tuberculosis. One who has used or heard the sound of a fine wood-plane can appreciate the sound. The sound may often vary in pitch between that of the wood-plane on soft pine and a soft rasping. It may be continuous or alternating through the entire period of inspiration, but is not usually heard on expiration.

The sound is usually heard best in the second or third intercostal spaces anteriorly, on the side affected, between the sternal line and the midclavicular line.

The abrasion of lung tissue or infiltration on the external surface or in the parenchyma of the lung which produces this diagnostic sound does not affect, or cause abnormalities of voice but affects the breath sounds of inspiration.

The normal inspiratory sound is a soft blowing murmur which can be very well imitated by placing the mouth and lips in position to articulate the letter "F" and drawing in gently to the end of inspiration.

Roughened breathing is often audible in infiltrated areas. The interrupted breathing which assumes a jerking or saccadate character (cog-wheel breathing) is looked upon as of importance in apical tuberculosis.

The abnormal inspiratory sound to which I have referred, is imitated by placing the lips and tongue in position as if to articulate the letter "T." Then make the sound "shlu" by taking a full slow inspiration in an undertone, or alternate as graphically described in figures 1, 2, and 3. This inspiratory sound may be continuous or interrupted so as to consist of one, two or three parts. Rarely it may consist of four parts.

The following diagram will, in a graphic way, express nearly the sound "shlu" as indicated by the shaded spaces.

The dark spaces represent the sound "shlu" heard during inspiration: 1 small, 2 medium sized, 3 large lesion.

The sound may vary in intensity from the finest sound expressed in the diagram to a loud sound as might be shown in 3. Studying clinically the condition of the lungs and of the pleura, immediate auscultation alone is of value in the early diagnosis of the incipient stage of pulmonary tuberculosis. It is true that the methods of inspection, thoracography, spirometry, palpation, mensuration, percussion, *x*-ray examination, examination of sputum, and exploratory puncture may be of value in leading to a diagnosis or a differential diagnosis, but valueless in arriving at an exact early diagnosis of beginning tuberculosis.

In cases of tachypnea or in cases of bradypnea, or in cases of dyspnea associated with asthma bronchiale, the "shlu" sound I have ascribed to incipient pulmonary tuberculosis may be submerged or entirely obliterated.

In the years from 1914 to 1921, I examined the lungs of 12,000 persons. This includes 3,000 volunteer enlisted men in 1917, and approximately 4,000 drafted men, in 1918.

The sign was looked upon as of importance for diagnosis of beginning pulmonary tuberculosis. Bearing this in mind, I found it to be confirmed in 90 per cent of the cases diagnosed as incipient pulmonary tuberculosis. It is with the preponderance of evidence that I affirm with confidence the diagnostic value of this sound.

603 Wright Building.

BACILLUS AEROGENES CAPSULATUS INFECTION COMPLICATING TYPHOID FEVER.

WITH REPORT OF A CASE.

By HENRY R. MULLER, M.D.,
pathologist, New York Hospital,
and
J. S. LINCOLN, M.D.,
New York,
II. Medical Division, New York Hospital.

SECONDARY infection with the *Bacillus aërogenes capsulatus* (Welch) as a complication in the course of typhoid fever is probably an infrequent occurrence, for only nine cases could be found by the authors in the literature. These cases may be divided into two groups; first, those without any perforation of the intestine, in which the gas bacillus, hav-

ing gained entrance from the gastrointestinal tract, presumably through an ulcer, produced a more or less general infection of the organs; and second, those in which perforation of the intestine had occurred, and in which the gas bacillus was demonstrated in the peritoneal exudate. In this second group, however, there was no generalized involvement of the viscera in any case, and the presence of the bacilli in the blood in the few instances noted may have been due entirely to a post-mortem invasion.

In the first group are the following cases. In 1900 Howard[1] reported a case (No. IV) of typhoid fever in which there had been no subcutaneous emphysema before death. Meteorism had been marked. At autopsy, however, there was subcutaneous emphysema, and gas-bubbles were found in the mucosa of the gall-bladder and bile-ducts, in the liver, spleen, kidneys, inferior vena cava, and portal veins. The excessive development of gas in the gall-bladder and the liver, and its paucity in the other organs and in the blood were regarded as evidence that the biliary tract had been the portal of entry.

In Howard's case No. VIII there also had been no subcutaneous emphysema observed before death, but there had been marked tympanites. At autopsy, subcutaneous emphysema was marked, and air-bubbles, due to the development of the gas bacillus, were found in the heart and blood vessels, and in the abdominal and thoracic viscera. In this case, a gastric ulcer was regarded as the portal of entry, because of the presence of gas cysts about the ulcer, and the presence of gas bacilli in its necrotic surface. Ulcers and hyperplastic Peyer's patches were present in the ileum.

Before this, in 1896, Welch and Flexner[2] (Case XXII) had reported a case of Howard's, of a man who died in the third week of typhoid fever. There was no tympanites present at death. At autopsy, extensive subcutaneous emphysema was present. The blood-vessels and the thoracic and abdominal viscera contained gas. Typhoid ulcers without perforation were found. No suggestion was made as to the probable portal of entry of the gas bacillus in this case.

A case reported by Bowen[3] very likely belongs here also. Unfortunately no laboratory findings, no statement as to whether an autopsy was performed, or other confirmatory evidence are presented. The statement is made that in the fourth week of a severe case of typhoid fever, emphysema commenced on the abdomen and spread throughout the body. It was followed in three days by death.

In the group of cases of typhoid fever with perforation and peritonitis, in which the gas bacillus was found in the peritoneal exudate, or in the exudate and in the blood, the following instances are on record. In 1896 Welch and Flexner reported three cases. In one, the gas bacillus together with streptococci and colon bacilli were demonstrated in coverslip preparations from the peritoneal exudate. Typhoid bacilli and colon bacilli grew in culture from the organs. Free gas was present in the peritoneal cavity, but none in the blood-vessels or viscera.

In the second case, gas was found in the peritoneal cavity, but none in the heart or viscera. Gas bacilli and colon bacilli were present in the peritoneal exudate.

In the third case, there was gas and an extensive fibrino-purulent exudate covering the peritoneal surfaces. Gas bubbles were present in the inferior vena cava, the systemic and portal veins, and in the right heart. Cultures from the peritoneal exudate showed gas bacilli, colon bacilli and streptococci. The gas bacillus was found also in the blood. Because the autopsy was performed as late as twenty-two hours after death, and because there were evidences of cadaveric decomposition, the gas found in the heart and vessels in this case was looked upon as due to a post mortem development of the gas bacillus.

Howard also reported one case belonging in this group. The patient had died in the fourth week of typhoid fever. Two perforated typhoid ulcers were present in the ileum, and several small ulcers were situated in the mucosa of the stomach. One of the latter showed, microscopically, gas cysts and large numbers of "large stout bacilli" in the necrotic material of the ulcers of the ileum. A few gas bubbles were found in the branches of the portal vein in the liver, and in the inferior vena cava. The other organs were free from gas. The peritoneal cavity contained gas, feces and a fibrino-purulent exudate, from which the colon bacillus and pyogenic cocci were obtained in culture. No anaerobic cultures were made, and the diagnosis of the presence of gas bacilli in this case rested upon the morphological appearance of bacilli found in coverslip preparations, and in the hardened sections of the stomach.

Hibler[4] isolated a gas bacillus (called by him the bacillus phlegmones emphysematosae Fraenkel), together with typhoid bacilli, colon bacilli, streptococci and staphylococci, from the peritoneal exudate of a case of perforated typhoid ulcer.

The cases cited above are the only cases found by the authors in the literature. Recently the authors have had an opportunity of observing a typhoid patient, in whom the gas bacillus infection, occurring in the third week of the disease, was followed in a very short time by death. There was no perforation of the intestine.

Case Report.—A white man, aged 29, was admitted to the New York Hospital on December 8, 1920, and died December 11, 1920. Before admission he had been confined to bed for two weeks with fever, headache, severe diarrhea, and anorexia. At the time of his admission he was well nourished, but appeared to be acutely ill. His face was flushed. There was no cyanosis. The abdomen was distended and tympanitic. The spleen was extended 6 cm. below the costal margin. There was a diffuse macular rash over the chest and abdomen that did not disappear on pressure. A few moist râles were heard over the bases of the lungs posteriorly. The red cells numbered 4,490,000, the white cells 2,400, polynuclears 70 per cent., lymphocytes 24 per cent., and large mononuclears 6 per cent. The systolic blood pressure was 100, the diastolic 66. The Widal reaction was strongly positive. The urine contained a trace of albumin, hyalin and granular casts. On the first two days in the hospital the temperature varied between 103° and 104° F.; the pulse rate between 108 and 120, and the respirations between 28 and 30. The treatment consisted of hydrotherapy, liquid diet, and enemata. A blood culture taken on December 9 remained sterile for twenty-four hours; after five days it was reported as being contaminated. On December 10 the patient became delirious. The temperature dropped at noon on that day to 101.2° F., the pulse rate rose to 136, but the respiration rate remained unaltered. Enemata relieved the abdominal distention.

On the morning of the 11th the patient seemed quieter and the stools were less frequent. The skin rash had not changed in appearance or distribution. Following a slush-bath at 4.30 P. M on this day he became restless, dyspneic, and slightly cyanotic. The lungs gave no physical signs of consolidation. The pulse was rapid (140), but was otherwise unchanged. The abdomen was not tender, and there were no signs of rigidity. An area of subcutaneous emphysema about the size of the palm of the hand was found in the right anterior axillary region. No similar areas could be found anywhere else. A needle was inserted into the subcutaneous tissue of this area for material to culture, but none was obtained. A blood count made at 5 P. M. showed a white cell count of 23,400, of which 60 per cent. were polynuclears, 29 per cent. lymphocytes, and 11 per cent. large mononuclears. The temperature rose to 105.4° F., the respirations to 40, and the pulse to 154. The respirations soon became shallow and infrequent, and the patient died at 7.25 P. M.

Autopsy.—The body had been kept in the icebox in the morgue overnight at approximately 10° C., and the examination was started seventeen hours after death. Post mortem rigidity was present in the extremities. The face was cyanotic and there were extensive cyanotic patches over the arms, chest, and abdomen. Subcutaneous air crepitus was easily elicited over the neck, thorax, and outer surfaces of the thighs. The abdomen was distended and tympanitic. There was a needle puncture wound in the lower part of the right side of the chest in the midaxillary line. Around it there was an irregular area of reddening of the skin about 20 cm. in diameter, with large blebs containing gas and serum. There was extravasation of blood into the muscles of the thorax beneath this area. A small needle puncture wound was present on the outer surface of the right lower lobe of the lung, and the pleura around it was stained with blood.

Innumerable small gas bubbles were visible in the subcutaneous tissues of the abdomen and thorax. When the peritoneum was nicked a large quantity of gas escaped with a pop through the opening. There was no perforation of the intestines, nor was there any inflammatory exudate present in the peritoneal cavity. The mesentery and the omentum were the seat of numerous gas-containing blebs. In the mesentery there were also many enlarged soft lymph-nodes, the majority containing bubbles of gas.

The pleural cavities were free from fluid and adhesions. The pleural coverings of the lungs were dark red. The lower lobes of the lungs were firm in consistency; the cut surfaces were dark red in color and gas bubbles in blood-tinged fluid could be easily scraped from the surfaces. The upper portions of the lungs were congested and spongy to the touch.

The heart was large and exceedingly soft and flabby. The left ventricle was dilated and contained gas. The endocardium of both sides, including the heart valves and the intima of the aorta, were stained diffusely red, due to the imbibition of hemoglobin. The heart valves were otherwise negative.

The spleen, much enlarged, was 25 cm. in length. It crepitated like lung tissue, and was extremely soft and easily torn. On the cut surface were seen extensive hemorrhages and numerous gas-containing cavities, which latter varied from a few mm. to 1 cm. in diameter. An accessory spleen, 2 cm. in diameter, in the gastrosplenic ligament, was likewise very soft and contained gas bubbles.

There were many gas bubbles in the perirenal fat tissue. The kidneys were very soft. Numerous gas blebs, closely packed together and pinpoint and pinhead in size, were present in the kidneys, confined chiefly to the cortex. The normal markings of the kidneys were destroyed.

Greenish post mortem discoloration was present on the lower surface of the liver. Gas bubbles escaped from the portal veins on the cut surface. Macroscopically, no gas blebs could be distinguished in the liver substance, and the liver lobules were fairly distinct. The gall bladder was negative.

The stomach and duodenum were negative. Close to the ileocecal valve were large typhoid ulcers which had sloughed considerably, but were not entirely cleaned out. Slightly higher up the ulcers were filled with grey necrotic material, showing beginning sloughing. Still higher up there were pink, hyperplastic Peyer's patches without necrosis. None of the ulcers extended very deeply. The mucosa of the colon was the seat of numerous hemorrhagic spots each about ½ cm. in diameter.

Permission to examine the brain was not obtained.

Microscopic.—Liver: The liver cords are greatly distorted, and the liver cells vary much in size and in their relation to one another. The nuclei stain faintly. There are numerous irregular round holes corresponding to gas cysts. Of these many contain fine granules of brown pigment. The cells themselves also contain many fine irregular vacuoles.

Kidneys: The nuclei of the cells of the convoluted tubules stain either very faintly or not at all. The nuclei of most of the glomeruli and of the collecting tubules, on the other hand, stain fairly well. The cytoplasm of the cortical epithelium stains poorly and has the appearance of simple necrosis. There are very many large cavities limited to the cortex, compressing the intervening tubules and glomeruli.

Lung: The structure of the lung is greatly altered, the alveolar walls being distinguishable only with difficulty. There is much serum present and numerous gas cysts. A large quantity of fine granules of brown pigment is scattered over the section. The red blood cells within the blood vessels are pale (hemolyzed).

Intestines: The ulcers have the usual features of typhoid ulcers. There is no inflammatory exudate on the peritoneal surface.

Sections of the liver, spleen, and kidneys show the presence of numerous large Gram positive bacilli resembling the bacillus aërogenes capsulatus in morphology. Sections of the ulcers in the intestine reveal numerous similar organisms in the necrotic material and in the wall of the intestine.

Bacteriological Examination.—Cultures from the spleen show the growth of an anaerobic Gram positive bacillus with the morphological and cultural characteristics of bacillus Welchii, and also of an actively motile Gram negative bacillus having the morphological and cultural characteristics of bacillus typhosus, and which is agglutinated with antityphoid rabbit serum in dilutions of 1:50 to 1:500.

Comment.—In view of the fact that the *Bacillus aerogenes capsulatus* is found in the gastrointestinal tract of the majority of individuals it is rather surprising that the occurrence of secondary infection with this organism in typhoid fever is not more frequent than is reflected in the literature. The necrotic material in the ulcers, one would suppose, would furnish a suitable medium for the development of the organism, but, undoubtedly, other conditions must be fulfilled before it can invade the blood or lymph stream. Just what these factors are is not entirely known, though it appears that in certain instances other organisms prepare the way for its invasion into the body.

On the other hand, the invasion of the gas bacillus may actually be as infrequent as the observations seem to indicate, *i. e.* the physical conditions in the typhoid ulcers, the resistance of the patient, or the virulence of the organism are such that invasion rarely occurs; or, the portal of entry is not opened to the gas bacillus by other organisms.

It seems quite certain that the invasion of the gas bacillus in the present case took place before the patient's death. About three hours before his death a small area of subcutaneous emphysema was discovered, and at the same time he was found to have a marked leucocytosis and a rise in temperature. There was nothing found at autopsy to account for this emphysema except the general gas bacillus infection. Although the entrance of the gas bacillus from the intestinal canal through an ulcer of the intestine could not be positively estab-

lished in this case, still from the findings this seemed most probable.

That he died soon after the appearance of this small area of subcutaneous emphysema tends to confirm the observation of Flexner that the maintenance of life is probably impossible after this organism has established itself in the blood and produced gas there. Extensive subcutaneous emphysema, therefore, is not found during the life of the patient, and a clinical diagnosis of gas bacillus infection in typhoid fever is, on that account, not often made. Much of the gas found at autopsy is probably a post mortem development, the amount depending, among other things, upon the time after death the autopsy is performed and upon the internal temperature of the body.

EXOGENETIC PRIMARY CUTANEOUS INFECTIONS.*

By SIGMUND S. GREENBAUM, M.D.,

PHILADELPHIA, PA.

ASSISTANT PROFESSOR OF DERMATOLOGY, POST-GRADUATE SCHOOL OF MEDICINE, UNIVERSITY OF PENNSYLVANIA.

In order to have a proper understanding of the commoner infections of the skin, the subject outlined by the committee, it is well to keep in mind the routes of infection. A description of the known exogenetic and endogenetic cutaneous infections, primary and secondary, and those in which the cutaneous system, in conjunction with other systems, is involved, forms half the text of such a volume as Stelwagon's, from which you may deduce its extent. Before proceeding to the exogenetic forms, it might be well to remark that practically all the infections having an internal or endogenetic origin, such as the cutaneous syphilides, tuberculomas, lepromas, are commonly quite distinctive clinically because of the cell infiltrations of which they are composed. As regards the infections of external origin, we find that they resolve themselves into two groups—those which are primary, such as true impetigo, ecthyma and ringworm, and those which are secondary, such as the infections following scratching in scabies, pruritus, eczema, etc. It is with the primary group that we are particularly concerned in this paper. Primary exogenetic cutaneous infections, like infections involving other body systems, may be caused by vegetable parasites from the highest forms (some species of mould or ringworm fungi, yeast fungi) to the lowest forms (the fission fungi) many of which, as you know have pathogenic properties. As the time allotted to the reading of this paper will hardly permit complete discussion of the long list of even common external primary skin infections and as discussion of one or two of these alone would hardly be satisfactory in my opinion, I thought it best to cover the subject in a more or less general manner.

Of all the multiple forms of cutaneous infections, there are naturally some that are more frequently seen than others; some are commoner in children than they are in adults (for example, ringworm, which is never seen in the adult, impetigo, infantile pyodermas, with its cutaneous and subcutaneous abscesses, which are extremely common in the marasmic infant) and vice versa, some are commoner in adults than in children (as for example sycosis, carbuncle, etc.); further some are commoner in the summer than they are in the winter; others are commoner in certain climates (mould fungus infection is much commoner in the tropical climates) and, finally, some are more frequently seen in the presence of certain abnormal systemic conditions (such as furunculosis, carbunculosis in diabetes, etc.).

But the frequency of a condition cannot characterize it by any means. It is partly for this reason that I hesitate to simply discuss one or two morbid entities as well as for the extremely important fact that as regards cutaneous diseases, the number of modes in which the skin can react to trauma (bacterial or otherwise) is so limited that you can readily see how objectively similar are many of the lesions produced by these organisms. By limitation of cutaneous reaction, I refer to the few possible types of primary elementary skin lesions (redness, papulation, vesiculation, blebs, tubercles, gummata, ulceration) and secondary elementary skin lesions (scales, crusts, scars, pigmentations). Thus it is that cutaneous lesions produced by very different organisms are clinically exactly alike. But aside from this similarity of the so-called typical lesions of an infection, similarity may develop during the course of the disease either from an admixture of varying amounts of blood or pus in various stages of formation, dirt, drugs applied, and what appears to be of paramount importance—virulence of the special strain of organism involved; the greater the virulence the more marked the inflammatory phenomena. Thus, for example, certain cutaneous syphilides may look exactly like an ordinary impetigo, the so-called impetigoform syphilide, a lesion indicative of recent syphilitic infection, like impetigo, usually occurs on the face and specially about the nasal and buccal orifices; a simple impetigo is often mistaken for a ringworm; a deep ringworm infection (called deep tricophytosis) may stimulate a coccogenic condition (parasitic sycosis and coccogenic sycosis); a pustular bromide or iodide eruption may simulate an ecthyma in the former, an acne in the latter. All of this simply goes to show how valuable the laboratory is in establishing a clear cut diagnosis, not only from an etiological but from a prognostic and curative viewpoint, but it must not be understood from this that the clinical diagnosis need always depend on the serology, the microscope and the culture tube.

In a general way it may be said, and this is specially true in cutaneous diseases as it is in ophthal-

*Read before Southeast Branch of the Philadelphia County Medical Society, October, 1921.

mology for example though to a greater degree, that they must be seen to be appreciated and recognized. It requires a pretty good imagination in my opinion and a thorough knowledge of skin anatomy and pathology (which is by the way a prime requisite in any case and from all points of view) to be able to properly visualize a skin lesion after reading or being told about it. Nevertheless since circumstances require it, let us attempt to visualize some of these lesions; the true impetigo, which is a streptococcic affair and which has been so exceedingly common this past summer, begins suddenly, usually in a child, on the exposed surfaces and not uncommonly from contact with some other child in the family presenting similar lesions. It starts as a red or erythematous spot, over which area there appears, within a few hours, a blister or bleb due to an accumulation of serum beneath the horny layer of the epiderm, between it and the mucous body or spindle cell layer. After a variable period of time, one to three days, depending on whether the lesion has been ruptured from scratching or otherwise or whether it has undergone a spontaneous evolution, its appearance changes. If torn off, there remains a red raw superficial excoriated nonulcerated surface which oozes some serum. This serum, which soon becomes purulent to a varying degree, after a time hardens and forms a crust. If left alone, the purulent fluid is to a certain degree absorbed, the remainder hardens, the epidermic elevation falls, becomes wrinkled, and a special sort of crust is produced. I say special in most cases, but it should be remembered that the classical yellowish crust, as if stuck on, as described in all text books, does not always occur, and besides a crust cannot characterize a dermatosis as we shall see. It is at this stage, particularly if there has been any tendency to hemorrhage into the bleb, that the lesion may be mistaken for an impetigoform syphilide. But in this latter case it will be found that after the crust is removed, and it is an axiom in dermatologic diagnosis always to remove a crust and see what is under it before making a diagnosis, it will be found that there is a distinct ulceration present. This rarely occurs in true bullous impetigo; furthermore there is an oozing papule present, due to the round cell syphilitic infiltration (no papulation occurs in true impetigo). With epidermization completed beneath the impetigo crust, this latter falls and exposes the delicate new skin which still has a slight pink color, indicative of a former inflammation, and which gradually disappears without leaving a mark. In many of these cases, where the bleb has been ruptured, central healing occurs first. In such cases the lesion is apt to be mistaken for a ringworm. But in ringworm, although the center may be clear, the peripheral border will be seen to be composed of individual active or dried vesicles, placed side by side, though sometimes confluent, whereas the border in impetigo is composed of the frazzled ends of a continuous epidermic separation.

I should like to discuss other streptococcic skin infections called streptococcias, as well as the cutaneous staphylococcias, morococcias (or the fission fungi infections), tricophytoses or mould fungi infections but the time lacks.

As regards the prognosis of these primary exogenetic skin infections, it may be said that the higher up on the biologic scale an organism is, the more difficult its destruction; the disease it causes is therefore more difficult to cure, lasts longer, and has a greater tendency to scar formation. Furthermore, it is important to recognize that its localization determines the facility with which it can be cured. Infections in the hairy areas of the body are much more rebellious than those involving the hairless parts. Thus ringworm of the scalp is far more difficult to cure than ringworm of the body; a coccogenic sycosis (which is really a staphylococcic folliculitis) is more persistent than a folliculitis of the scalp.

Treatment of these conditions is generally easy; some, however, are more easily managed than others. but all can be cured. The treatment is both external and internal, with the latter as the most important. The increase of the patients vitality is often indicated, with proper food and hygiene. As regards drugs, internally, only potassium iodide which is used in the yeast fungi infections (Bastomycosis) is of value. The alkalis occasionally seem to have a beneficial effect in the deep fission fungi infections, notably furunculosis. Externally, irrespective of the cause of the lesion, never apply an active medicament until all crusts and scales have been removed as action is wanted on the affected areas themselves. Many make the mistake of writing a prescription for some salve and telling the patient to apply it to the affected areas. For higher organisms (ringworm and yeast) iodine is a specific. This has been amply proven by experimental work carried out at the Dermatological Research Institute of Philadelphia. It is applied in the following manner: 1 part tr. iodine in 9 parts of alcohol or ½ per cent. iodine ointment with 1 per cent. betanaphthol. In the treatment of fission fungi (cocci, etc.) calomel in 1-3 per cent. ointment is the best with 3-5 per cent. yellow oxide of mercury second best. Calomel, insoluble though it is, is one of the best germicides we have.

1714 Pine Street.

Medicolegal Notes.

Privileged Communications—Waiver.—The Mississippi Supreme Court holds that, under the statute of that State making a physician incompetent to testify to facts which come to his knowledge by virtue of his being employed by his patient as a physician, the patient does not waive the privilege because he introduces another physician who testifies for the patient about the same facts. It is held improper practice in such a case to permit the physician to testify at all about such facts even in the absence of the jury. The proper practice in Mississippi courts is to ascertain whether the facts were learned because of the relation, and, if so, to exclude the evidence.—United States Fidelity & Guaranty Co. v. Hood (Miss.) 87 So. 115.

Unlawfully Assuming to Practice Medicine.—In the trial of an indictment charging the defendant with being unlawfully engaged in the practice of medicine and surgery, the Pennsylvania Superior Court sustained a conviction where the evidence established that the defendant, who was not a licensed physician, examined patients by physical tests, made inquiry of their past condition, examined the pulse and tongue to diagnose the cause of the real or alleged malady, after which he prescribed his special remedy to afford relief. It has been uniformly held that where one holds himself out as competent to prescribe, he is engaged in the practice of medicine, notwithstanding the remedy prescribed by him is one of his own invention or compounding.—Commonwealth v. Read, 76 Pa. Superior Ct. 202.

ACTIVITIES OF THE UNITED STATES PUBLIC HEALTH SERVICE.

IN the fiftieth annual report of the United States Public Health Service, covering the one hundred and twenty-third year of the existence of the service, the Surgeon General outlines the following outstanding activities: (1) The prevention of the introduction of diseases into the United States, or from one State to another State; (2) the investigation of diseases of man and stream pollution; (3) supervision and control of biological products; (4) public-health education, and (5) the operation of a hospital service for its beneficiaries, including disabled ex-service men and women.

In connection with national and interstate quarantine it is stated that the service now operates all of the war-time quarantine stations in the United States, and it has thirty-five officers stationed in Europe to enforce certain quarantine restrictions in regard to ships and passengers bound for ports of the United States. The "epidemic fund," appropriated by Congress for the control of cholera, yellow fever, plague, typhus fever, and the like, has been used by the Public Health Service for the prevention of the introduction of these diseases into this country, or from one State to another. Measures for the control of plague, the presence of which in Florida, Louisiana, Texas, and California was noted in the last annual report, have met with such success that the operations of the service in this connection have been reduced. In noting the fact that no epidemic of serious proportions has occurred in the United States during the year covered by the report, the Surgeon General warns that, owing to the present financial depression, those diseases which have a distinct relation to economic conditions will show an increase in prevalence unless the financial conditions present early and material improvement.

In the line of scientific research the service has continued its demonstrations in rural sanitation, and its investigations of child hygiene, industrial sanitation, influenza, pneumonia, pellagra, trachoma, tuberculosis, biological products for the prevention and cure of diseases of man, pollution of streams, and other allied activities. Among these manifold activities, which are carried on by the Scientific Research Division, one of the most important, it is held, is that connected with cooperative rural health work. Despite the fact that the appropriation for this work made available by Congress was less than ten per cent. of the amount necessary to enable the Federal Government to accept opportunities which were presented at the beginning of the fiscal year through offers from State and local authorities to enter into cooperation in due and reasonable proportion to develop demonstration projects in rural health work, such cooperative projects were carried out in thirty-eight counties in fifteen States. The investment of Federal funds in these undertakings was covered with odds of over eight to one for the support of the work. The Surgeon General calls attention, in this connection, to the stimulating effect of the Federal cooperation. In the development of whole-time rural health service in the United States the Surgeon General reports substantial progress, despite the general economic depression. According to data collected by the Rural Sanitation Office from the State health departments, there were in the United States only 154 counties (over 50 per cent. rural) which, on January 1, 1921, were provided with local health service headed by whole-time county health officers. It is pointed out that this means that less than six per cent. of our rural communities are provided with local health service approaching adequacy for the protection of the men, women, and children against readily preventable health demotion, premature death, and economic disaster resulting from costly sickness. Such a situation, the Surgeon General declares, is of grave importance to the individual citizen, to the local community, and to the whole nation, and should be a matter of acute concern with our local, State, and national governments. Rural health work, on account of distances to be covered and other obvious factors, is relatively more expensive than urban health work, and without assistance and stimulation from central agencies, he says, it is considered clearly established that individual citizens and local communities in our rural districts will not make the progress in the carrying out of health measures which is critically needed. A strong plea is made for proper and proportionate assistance by the National Government to the States for the promotion of cooperative rural health work. For, says the Surgeon General, "if the Federal Government has a right to cooperate with the States in any line of work, the indication is definite for it to do much more than it is and has been doing for the promotion of cooperative rural health work."

While sympathizing with Surgeon General Cumming in his natural desire to promote the health of the country, we believe that such work should be done by the individual States without financial aid from the Federal Government. That provision bringing as it necessarily will Federal supervision of interstate activities, is one of the worst features of the recently enacted Sheppard-Towner bill. As Governor Miller of New York said recently, in an address before the Bar Association, referring to

that bill, it is time "to utter a note of warning against the present tendency to build up a Federal bureaucracy to supervise State activities under the guise of Federal aid, and thus by indirection to change our system of Government and to destroy the limitations upon the exercise of Federal power fixed by the Constitution."

A VERY GRAVE CHARGE.

Two weeks ago the MEDICAL RECORD commented on a resolution introduced into Congress by Representative Volk calling for a Congressional investigation of the narcotic drug problem and of the present administration of the Harrison law. The resolution stated that many of the Federal and State rulings "point to an organized conspiracy on the part of certain administrators and physicians to drive narcotic drug addicts into established sanitaria purporting to treat and cure narcotic drug addiction." In a speech made by the author of this resolution, in the House of Representatives on Jan. 13, this charge is amplified and made more specific. Referring to the tendency in carrying out the objects of the Harrison law to substitute for the provisions of the act arbitrary administrative opinions expressed in rules and regulations which amount to practically a repeal and nullification of the law itself, Dr. Volk said:

> These rules and regulations have been promulgated by those in charge of the administration of the Harrison law upon the representation and statements coming as the official pronouncements of the New York City Board of Health, presented by a particular small group or clique among whom stand out prominently the names of Royal S. Copeland, health commissioner of the city of New York, Drs. E. Elliot Harris, S. Dana Hubbard, Alfred C. Prentice, and a lawyer. . . . Reliable records, reports, scientific information, and experience have been swept aside by these men and in their place has been set up a campaign of publicity intended in the end to benefit this small coterie who seek to control the avenues of narcotic treatment throughout the country.
>
> The agitation emanating from New York City from these men and the department of health is spreading over the entire country and knowingly or unknowingly has evaded and ignored sound medical findings. As a substitute for open discussion of known medical facts there has been set up a propaganda for the incarceration of all drug users, their treatment by routine methods, and complete elimination of the family doctor. An undeniable effort is now being made whereby physicians are to be denied any discretion and power in the prescribing of narcotic drugs and to force all those addicted to the use of these drugs into hospitals exploiting questionable "cures."
>
> I charge that this propaganda has been carried on by Dr. Royal S. Copeland, health commissioner of New York City; Dr. S. Dana Hubbard of the New York City Health Department, and Drs. E. Elliot Harris and Alfred C. Prentice, the last two active in the councils of the New York County Medical Society and the American Medical Association. I further charge that Arthur D. Greenfield, a lawyer of New York City, has aided and abetted the propaganda above mentioned.

A similar charge was made in the report of the Committee on Legislation of the Medical Society of the State of New York, published in the *New York State Journal of Medicine* in June, 1921. Referring to one of the vicious bills introduced into the Legislature with the alleged object of furthering the treatment of drug addiction, the report says:

> Where the scheme is not horrible and inhumane it is ridiculous and at the same time sinister. The bill is not a local one; a studied attempt is being made to effect it into law in many States, and an earnest effort is being prosecuted to have the regulations promulgated by the Federal Bureau having charge of the Federal Harrison Act to give that act the same force as this bill would have if it became law. *Verbum sapienti sufficit!* The first Smith bill classes drug addiction among the infectious and communicable diseases presumably to give the same power to boards of health and health officers to commit and hold in isolation drug addicts as they now exercise under the same section in cases of smallpox, diphtheria, and other infections.

And again, still treating of narcotic drug legislation:

> The various committees that have been appointed by national and State bodies to "investigate" these subjects apparently have had as their foremost requirement for membership thereon the proof of lack of experience with the subject to be considered by them and their reports have always been entirely standardized and apparently written *ad hoc* by an interested group comprising not more than ten men in the medical profession and a couple of lawyers. Their investigations have not been unbiased, their findings have not been judicial, and their reports have largely been *ex parte* formularizations. That a Senator of the State of New York should be obliged to state at a public hearing that a bill which he had been asked to introduce, and which had been approved by this State Society, was such in its nature that he felt aggrieved and imposed upon, and immediately withdrew this bill, is a fact to excite surprise, grief, and indignation. . . . Most important of all is it that the medical profession clear itself of all the groups and cliques who are striving not mainly for the benefit of the public and the profession, but for other and ulterior motives.

As this report gives no names, we are left to conjecture whether the "groups and cliques" referred to in the report and in the speech are the same or not. If they are, five men in the medical profession and one lawyer appear to have dropped out, since Representative Volk mentions only these four doctors and one other and a lawyer.

The MEDICAL RECORD is very loth to believe, and cannot believe unless further proof is brought forward, that these men, who are regarded by their friends as honorable members of an honorable profession, could be guilty of the despicable practices with which they are charged in the quoted remarks and elsewhere in Representative Volk's speech. But since the charges have been made publicly by a physician and a representative from this State in Congress, the men named can do no less than disprove them. Officials of the Board of Health of this city and officers of the Medical Society of the County of New York cannot be willing to rest under any such grave imputation as this.

THE PATHOLOGY OF TENONTITIS.

PRIMARY inflammation of the tendons has been studied experimentally by several observers, notably Feltz, Leprince, and Ginsburg, in frogs and rabbits. Their results are alike in all the essential points. The changes in the nutrition resulting from the trauma first act on the protoplasm of the cell elements which increase in size and becomes granular. Their nuclei are less apparent while their envelopes often rupture and the protoplasmic contents infiltrate between the

tendon fasciculi. In this zone of degeneration the deformed and granular cells become glued together in opaque columns and then undergo atrophy. According to Ginsburg a process of regeneration is almost contemporaneous with that of degeneration; that is to say, at the same time that atrophy and absorption of the elements take place, new elements are produced by proliferation of the nearest adjacent cells. These proliferating cells are larger, send off multiple prolongations, are arranged in regular series, and reproduce the first phases of tendon development. Changes arising in the tendinous fibrillæ are not so well known. They consist in swelling of the fibrillæ and albumino-fatty degeneration.

Lejars believes that much the same phenomena arise in the pathology of tenontitis in man, and he divides the process into plastic and suppurating. The tendon is white, opaque, and its surface is dull; it forms a more or less thickened edematous cord, infiltrated with embryonal cells; granular buds cover its surface in plaques or in lines and dip down between the fasciculi. They become fused with the granulation tissue of the wound when the tendon is denuded in a purulent focus; later on they become organized and having become fibrous they create numerous adhesions between the tendon and skin. In suppurating foci the tendinous tissue itself becomes infiltrated with pus; it is gray in color, soft, and pliable. Unfortunately, in this classification Lejars makes no distinction between inflammation of an exposed tendon and tenontitis without injury to the integuments.

Studying inflammation of the tendo Achillis, Raynal insists upon three anatomical considerations: (1) On the existence of a fibrous space formed by the doubling of the aponeurosis of the tibialis posticus; the superficial layer passes behind the tendo Achillis while the deep layer unites on each side of the tendon, forming a dihedral angle; (2) on the existence in this fibrous space of connective tissue containing masses of fat; this cellulo-adipose tissue is completely separated in the normal condition from the subcutaneous connective tissue by the deep superficial aponeurotic layer, while the deep layer separates it from the deep cellular tissue; (3) on the absence of the synovial membrane which normally facilitates movement of the tendo Achillis in the fibrous sheath. These considerations are worth bearing in mind. They resemble the arrangement found at the lower part of the biceps in the arm. The tendon of this muscle lies in a space filled with cellulofatty tissue, much like that surrounding the tendo Achillis. Now, when tendons are not surrounded by a synovial covering, the interstices of the tendon bundles are directly continuous at the periphery with the peritendinous tissue, and it is from the latter that they receive the elements of their nutrition. Sappey shows that the blood vessels of the tendons are derived from the peripheral venules and arterioles and dip into the interfascicular spaces. The intimate relation existing between the tendon and its cellular atmosphere is therefore evident, and a tenontitis cannot occur without a certain amount of peritenontitis, and vice versa.

The older writers were well aware that when inflammation of an organ did not end in suppuration, induration took place, so that for them, sclerosis was synonymous with chronic inflammation. The essential fact of all chronic inflammation is proliferation of the preexisting connective tissue whose elements multiply abnormally, and progressively take the place of the elements belonging to the inflamed organs. Now, the intimate structure of the tendons comprises not only parallel fibers, but numerous connective tissue cells—the so-called tendon cells. These are exposed to proliferation upon the occasion of the slightest inflammation, but this is relatively long in taking place on account of the scanty vascular supply. In structures so compact and with such poor vascularization as the tendons, it can be readily conceived that a purulent exudate would be produced with difficulty. Then inflammatory processes are almost always proliferative and characterized by the development of induration—sclerosis.

"WHY IS THE WASSERMANN?"

In an article with this title in a recent number of the Medical Record (Dec. 31, 1921), Dr. Stone has put his finger upon one of the weakest spots in modern medical practice, one to which we have often had occasion to refer in these columns. This is the tendency of the physician, perhaps we should say the younger physician, to rely for his diagnosis upon the report of the laboratory rather than upon his own careful study of the patient and thoughtful consideration of the possibilities and probabilities in the case.

"No physician has any right to make or exclude a diagnosis of syphilis upon the Wassermann reaction alone." That is obvious, but most of the discredit which has fallen upon this test is due to this practice, which is more largely followed than is generally realized. Some of it is probably unconscious, for although some men on direct question will freely admit the truth of the statement, their conversation will show that they actually consider a positive Wassermann reaction as proof of the presence of syphilis. The defects of the Wassermann reaction, and of other laboratory procedures as well, are realized, as a rule, only by those who have had laboratory experience. The tendency of the clinician is to attach to them much more importance than they deserve. It is not our desire to belittle in any way the value of the laboratory to the clinician but to emphasize that laboratory reports can attain their greatest value only when intelligently correlated with the information obtained by the clinician himself. The laboratory worker must impress this fact upon the clinician, not baldly but with suggestions designed to help in the solution of the clinical prob-

lem. It is by such aid that the "professional" laboratories may be expected to demonstrate their superiority over the "commercial" laboratories. But further, the laboratory worker must see to it that all procedures are carried out in his laboratory with the care that their importance demands. Careless work here will result in error even more quickly than at the bedside. It is conceivable that confusion of specimens may occur in even the most carefully managed laboratories, but it should be exceedingly rare. In every case in which the result of the test does not conform to the clinical expectation, the laboratory must hold itself obligated to repeat the examination in order to confirm the result. We cannot believe that careless laboratories can continue for long. Sooner or later their sins will find them out and they will perish from lack of material.

So far as the technique of the Wassermann reaction is concerned there is great need of uniformity before the results obtained in different institutions can be considered comparable. Kolmer and his assistants have done pioneer work in this field and have published a number of studies designed to determine the best procedures in each step of the test. They have evolved a technique based upon these studies, one which is not a short-cut to rapid reports but most carefully considered in all of its details. It is now being tried out in a number of different laboratories to determine whether it is worthy of becoming a standard technique for general use. Whether the method finally adopted be Kolmer's or that of some other worker we must eventually adhere to some uniform method if we are to enable the clinician to expect uniform results. But, above all, it must be emphasized that the Wassermann reaction is not a "test for syphilis." A positive test is *one* of the symptoms of syphilis, perhaps one of the most constant symptoms, but the physician who insists on considering it a pathognomonic symptom is not treating his patients fairly. There is no royal road to success in medicine any more than in other callings. Hard work and the intelligent use of all of the tools at his command are still essential elements in attaining real success.

The Prognosis of Influenza Bronchopneumonia.

In influenza epidemics it is often very difficult to make a certain prognosis for the bronchopneumonias. To remedy this deficiency one can only note the agreement of certain finds with the issue of the case. One may use for this purpose a variety of data, as the area of dullness, rales, and bronchial breathing; the temperature, pulse, and respiration; the presence of unilateral or bilateral symptoms and so on. In such a research the conclusions apply only to the complications of influenza and not to ordinary pneumonia. Dr. Bié of Copenhagen publishes a study of this sort in the *Acta Medica Scandinavica* for Dec. 5, 1921, lv, 6, in which over 1000 cases of influenzal bronchopneumonia are analyzed. The total number of deaths was 234. This large loss of life was due in some degree to the fact that many of the women were pregnant, for the death rate is 2½ times as great in the gravid. There were also 55 patients with heart disease in which the case mortality was very heavy. It is, of course, necessary to leave the gravid and cardiac patient out of the statistics. A toxic factor, as shown by the presence of jaundice, albuminuria, and the behavior of the temperature, pulse, and respiration, means a bad prognosis, but it is not always easy to isolate these cases by the temperature, etc. Thus it is easy to make a good prognosis from an improvement in the pulse and temperature, but not so simple a matter to make a bad prognosis if these seem unfavorable. Half of those who breathed 34 and upward on admission died, while if the breathing was below 34 recovery was the usual outcome. This difference was not dependent on whether the pneumonia was single or double, but inhered in each form, although naturally *per se* the prognosis is much better for single pneumonia. In all pneumonias with respiration above 40 on admission the prognosis is grave, and the more rapid the breathing the worse the outlook.

The Remote Mortality of Epidemic Encephalitis

There is as yet not much literature upon this subject, although a large body of facts has been assembled on the sequelæ of this affection. The prognosis for recovery *quoad vitam* after the danger has passed is generally regarded as good. None of the sequelæ, such as neurasthenia, pseudo-Parkinson's disease, organic dementia, psychoses, paralyses, etc., appears to be straightway fatal. It is therefore of interest to read the report in the *Revue médicale de la Suisse romande* for December, 1921, xli, 12, by Repond, of two late fatalities attributable directly to the disease, which agree so closely among themselves that the author reports but one of them. The patient was a man of 67 who went through two attacks of grip, in 1918 and 1919 respectively. In both instances the malady was accompanied by somnolence which was much less marked the second time. The man was not right mentally after this last experience and exhibited somnolence, torpor, headache, pareses, and visual hallucinations without insight into their falsity. The condition was at first progressive and differed from ordinary acute encephalitis in the absence of fever and prostration. This state of affairs, which persisted for two months and then disappeared spontaneously, is, of course, to be regarded as an immediate sequela. The reappearance of the syndrome was two years later, when he was stricken suddenly, and in a few days was delirious, dying on the fifth day. Autopsy appeared to show that the late recurrence of cerebral symptoms with fatal outcome was due to the anatomical evolution of small foci of encephalitis which had led after two years of relative health to destructive alterations.

News of the Week.

Yellow Fever in Vera Cruz.—The Health Department of Mexico City denies the alarming reports on the yellow fever situation in the State of Vera Cruz which have appeared in the daily press. Few fever cases exist. The Health Department has a number of doctors and nurses in the State of Vera Cruz studying the situation,

which is regarded as very favorable. It is thought that reports of a slight increase in malaria in the coast countries, where the disease is always prevalent, have probably been misunderstood.

Influenzal Pneumonia in New York.—According to statements given out by the New York Health Department, 366 cases of influenza were reported on January 26 and 203 on the following day. During the week preceding this date the number of cases of influenza reported to the Health Department increased daily. Health Commissioner Copeland makes the statement that he thinks the city is suffering from a mild epidemic of pneumonia rather than of influenza, and advises the use of a new pneumonia vaccine which Dr. William H. Park has produced at the Department Laboratories. Dr. Copeland states that this vaccine was tried on policemen in the influenza recurrence of 1919 and on the inmates of prisons and other institutions. The laboratory of the Health Department is making the vaccine in considerable quantities and arrangements are under way for its distribution to private physicians. For the benefit of those who cannot afford the services of a private physician such vaccines will be given at public dispensaries.

England and Wales Have Healthiest Year.—Last year was the healthiest on record in England and Wales, according to the Register-General's provisional figures. The death rate was only 12.1 a thousand. The birth rate, however, was less satisfactory, being 22.4, the lowest recorded, except for the war years. The infant death rate was 83 a thousand, the lowest of any year except 1920.

Metropolitan Life Reports Fall in Mortality Rates.—In an address delivered on Jan. 27 before the company's managers from all over this country and Canada, President Haley Fiske of the Metropolitan Life Insurance Company stated that the mortality for the year 1921 had fallen off 13.7 per cent. from that of 1920. The decrease in deaths from influenza was shown to have been 83 per cent., from pneumonia, 37.3 per cent.; from influenza and pneumonia combined, 52.9 per cent.; from typhoid fever, 1.5 per cent.; from measles, 63.5 per cent.; from whooping cough, 40.9 per cent.; from tuberculosis, 16.5 per cent.; from Bright's disease, 5.8 per cent; from diseases of the heart, 1.7 per cent., and from diseases relating to child bearing, 15.2 per cent. There were increases during the year in deaths as follows: From scarlet fever, 15 per cent.; from diphtheria, 5.4 per cent.; from suicide, 23 per cent., and from homicide, 13.8 per cent. Industrial mortality figures for 1921, compared with a like period of one decade ago, show an improvement which, measured in terms of lives, means the saving of 55,000 lives. The health work done by the company among its policyholders was considerably extended. More than 25,000,000 health pamphlets and leaflets were distributed during the year, and the company's nurses made 2,136,000 visits to sick industrial policyholders.

Scarlet Fever Closes Tenafly Schools.—The closing of the public schools for an indefinite period and the barring of all children under 16 from motion picture shows because of the prevalence of scarlatina was determined upon at a meeting of the Board of Health of Tenafly, N. J., on Jan. 23.

Federal Act Planned to Check Drug Evil.—At a conference held recently at the Health Department, attended by New York City and County officials, it was the consensus of opinion that the increase in the use of narcotic drugs in this city and State will be prevented only by the Federal Government putting a limit on the importation of habit-forming opiates which reach this country through legitimate routes or smuggling channels. Chief City Magistrate William McAdoo, Dr. James A. Hamilton, Commissioner of Correction, Bird S. Coler, Commissioner of Public Welfare, and Dr. Copeland were appointed a committee to draft a proposed amendment to the Federal drug law to be introduced in Congress in the near future. It will be recommended in the proposed amendment that the Federal Government take over the manufacture of habit-forming drugs and distribute them through the Public Health Service. Illegal handling of narcotics will involve a severe jail penalty.

Assembly Advances Hospital Bill.—The measure designed to provide that the State Hospital for the treatment of discharged soldiers suffering from mental diseases shall be open to the care and treatment of all persons and shall be known as the Brooklyn State Hospital, Creedmore Division, was advanced to the order of final passage in the Assembly on Jan. 24.

New Buildings for Medical School.—An offer by Samuel Mather of Cleveland to pay for the construction of new medical school buildings has been accepted by the trustees of the Western Reserve University. The present estimate places the cost of these buildings at $2,500,000. This gift, together with previous ones, will make Mr. Mather's endowments to the university total more than $4,000,000.

Offer of $100,000 for Cancer Cure.—An offer of $100,000 "to the graduate or student of any recognized university who within five years after date is the first to discover a medicinal treatment for the effective cure of cancer" was made recently by Lord Atholstan, proprietor of the Montreal *Star*. The decision is to be made by the Royal College of Physicians and Surgeons, London, England. The offer, which was made "to help in stimulating the work of research throughout the world," may be renewed.

Public Health Clinic for Ohio Town.—A public health clinic has been established in East Liverpool, Ohio, under the direction of the Board of Health. Funds to meet the cost of conducting the work have been raised through the efforts of the Chamber of Commerce and the Trades and Labor Council, cooperating with labor unions, merchants, and manufacturers.

An Official Organ of the County Medical Society.—The first issue of *The New York Medical Week*, the official organ of the Medical Society of the County of New York, published under the supervision of the Committee on Civic Policy, made its appearance on Jan. 21, 1922. Its aim is to supply a news medium for the medical activities of New York—announcement of medical society meetings, hospital and medical school news, legislative bills

and comments thereon, etc. In their salutatory the sponsors of the publication state that it is their aim to represent the profession truly. They say: "To that end we have established a 'Public Forum,' and it is our hope that here in the general expression of opinion and discussion of conflicting views we may determine the sentiment of the body we represent. Our readers are cordially invited to send their contributions for publication in this column." If this offer has no string to it we look for some interesting correspondence in this new publication, which will carry no scientific or technical articles.

Hospital Notes.—Plans for remodeling the Bronx Hospital for the treatment of ex-service men have been approved by the Treasury Department and it is hoped to have the hospital ready for occupancy by March 15, 1922. There will be 1800 beds and the remodeling will cost approximately $700,000. The hospital will be for the treatment of general cases.

Roosevelt Hospital, New York, is to have an eight-story addition to its building at Fifty-ninth Street and Ninth Avenue. The estimated cost of the new structure is $1,000,000.

A new soldiers' hospital, to cost over $1,000,000, is in the process of construction in Milwaukee, Wis. The new institution will include eight buildings and will accommodate 700 patients.

Two valuable lots in Hot Springs, Ark., have been given by the United States Government to the Leon Levi Memorial Hospital to be used as a site for additional hospital buildings. The hospital is to be maintained by the B'Nai B'Rith Society.

Work has been begun on the new $400,000 private ward of the New Haven (Conn.) Hospital. It is expected that the building will be completed in the course of a year, when it will be one of the most modernly equipped private wards in the country.

The Southeast Arkansas Hospital Association plans to build a $100,000 hospital representing five or six southeastern Arkansas counties. The town of Crossett has offered a building site free in order to secure the new edifice.

The North Carolina Baptist Hospital Commission had prepared plans and specifications for a hospital to cost approximately $150,000. The institution is to be located at Winston-Salem and it is expected that the building will be ready for occupancy by December 1, 1922.

First Child Welfare Building Opens.—The Board of Child Welfare has opened its administration building at 145 Worth Street, New York. The board is now caring for 25,000 children and 7500 mothers, at a cost of $4,000,000 annually, its aim being to keep the children in homes is as far as is compatible with their best interests. The plan of caring for dependent children in their homes whenever possible has been shown to be not only a great saving financially, but has also brought other advantages over the old institutional method. Children under the care of the board have been practically eliminated from the Children's Court, the Society for the Prevention of Cruelty to Children, and the Police Department, to say nothing of hospitals and sanatoriums.

Retirement of Professor Darier From Hospital Practice.—This distinguished dermatologist is the third Parisian practitioner to be retired recently from hospital service by reason of the age limit, the others being Brocq and Thibièrge. On the occasion of his departure from the Hôpital Saint-Louis Dariér's pupils and friends honored him with a medal and bust, the work of distinguished artists, both physicians—Professor Richer and Dr. Sabouraud. The ceremony took place in the historical hall of the hospital museum. Professor Darier pronounced an allocution of a moving character in which all of his characteristic qualities of modesty, benevolence, gentle irony, and kindness were reflected.

Dr. A. B. Musa of Webster, N. Y., is ill with typhus fever at Orenburg, Russia, where he has been engaged in Russian relief work.

Dr. C. N. Sisk of Athens, Ga., has accepted the position of public health officer of Winston-Salem, N. C., and will enter upon the duties of the office immediately.

Dr. D. T. McCall has been named president of the Mobile County Board of Health.

Dr. Albert Robin has been reelected chairman of the medical board of the Physicians' and Surgeons' Hospital of Wilmington, Del.

Dr. Florence L. McKay, recently Assistant Director, Division of Child Hygiene, Children's Bureau, U. S. Department of Labor, has been appointed Director of the Division of Child Hygiene, New York State Department of Health.

Medical Society Elections.—THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK, at its meeting held January 16, 1922, elected the following officers for the ensuing year: *President*, Dr. George L. Brodhead; *Recording Secretary*, Dr. E. E. Smith; *Chairman for Borough of Brooklyn*, Dr. Robert E. Coughlin; *Chairman for Borough of Richmond*, Dr. William Bryan.

THE DUTCHESS COUNTY MEDICAL SOCIETY, at its meeting held in Poughkeepsie, N. Y., Jan. 11, 1922, elected the following officers for the ensuing year: *President*, Dr. Joseph Vigeantz, Red Hook; *Vice-President*, Dr. Charles Lane; *Secretary and Treasurer*, Dr. H. P. Carpenter; *Associate Secretary*, Dr. Aaron Sobel.

THE ONEIDA COUNTY MEDICAL SOCIETY, at its annual meeing held in Utica, N. Y., Jan. 10, 1922, elected the following officers for the ensuing year: *President*, Dr. Andrew Sloan; *Vice-President*, Dr. D. H. Roberts; *Secretary*, Dr. William Hale, Jr.; *Treasurer*, Dr. Hyzer Jones; *Librarian*, Dr. T. Wood Clarke.

THE MONTGOMERY (ALA.) MEDICAL SOCIETY, at its regular meeting on Jan. 14, 1922, elected the following officers for the ensuing year: *President*, S. D. Suggs; *Vice-President*, Dr. Virgil Dark; *Secretary*, Dr. Fred Reynols; *Treasurer*, Dr. F. C. Stevenson; *Censor*, Dr. Fred Wilkerson.

THE GLENDALE (CAL.) PHYSICIAN'S CLUB recently elected the following officers for the ensuing year: *President*, Dr. G. H. Westphal; *Vice-President*, Dr. Laura Brown; *Secretary*, Dr. Henry Harrower.

THE WASHINGTON COUNTY (ARK.) MEDICAL SOCIETY, at its annual meeting held at Fayette, Jan. 6, 1922, elected the following officers for the ensuing year: *President*, Dr. Charles R. Swift,

Elkins; *Vice-President*, Dr. J. S. Cannon, West Fork; *Secretary*, Dr. F. R. Morrow, Fayetteville; *Treasurer*, Dr. J. R. Southworth, Fayetteville.

THE SEBASTIAN COUNTY MEDICAL ASSOCIATION, at its annual meeting held at Fort Smith, Ark., elected the following officers for the ensuing year: *President*, Dr. A. F. Hoge; *Vice-President*, Dr. Everett Moulton; *Secretary*, Dr. W. R. Booksher, Jr.; *Treasurer*, Dr. H. H. Smith.

Obituary Notes.—Dr. MARCUS J. LEVITT of Brooklyn, N. Y., a graduate of Baltimore University School of Medicine in 1900, and attending aphthalmologist to the Jewish Hospital, died of meningitis in that institution on January 25, at the age of forty-four years. He was also ophthalmologist to the East New York Dispensary and the Jewish Orphan Asylum.

Dr. WARD BEECHER WHITCOMBE, a graduate of New York University Medical College in 1899, died from blood poisoning on Jan. 10, at the age of sixty-four years.

Dr. WILLIAM HENRY RODGERS of Pittsburgh, Pa., a graduate of Jefferson Medical College in Philadelphia, in 1903 and a veteran of the Spanish-American War, died of pneumonia on Jan. 13, at the age of forty-three years.

Dr. JOHN E. PERRY, a graduate of the College of Physicians and Surgeons, Columbia University, in 1873, died at his home in Wakefield, R. I., on Jan. 5, at the age of seventy-three years.

Dr. GILES ANDREW FIKE of Dundaff, Pa., a graduate of Jefferson Medical College, Philadelphia, in 1876, died in a local hospital on Jan. 6.

Dr. JOHN CHRISTOPHER O'CONNOR of Manchester, N. H., a graduate of Bowdoin Medical College in 1905, died on Jan. 6, at the age of forty-three years.

Dr. WILLIAM GLEN ALLAN, retired, died at his home, Glen Allan, near Greenville, Miss., on Jan. 12, at the age of eighty-one years. He was a surgeon in the Confederate Army, and later served as county health officer of Washington County and as a member of the County Pension Board.

Dr. GEORGE ALVIN HILL died at Merion, Pa., on January 23 at the age of sixty-nine years. He was graduated from the medical department of the University of Pennsylvania in the class of 1874. He was a member of the Philadelphia County Medical Society, the Medical Society of Pennsylvania, and the American Medical Association.

Service Bureau.

Regular subscribers to the MEDICAL RECORD who desire information on any professional matter are invited to send their inquiries to the office of publication. Replies will be sent by mail as promptly as possible. Questions and answers of general interest may be published from time to time. When abstracts of articles from other journals are furnished the cost of typewriting will be charged.

Purchases will be made of articles of any description wanted by subscribers; a check sufficient to cover the cost should be sent with the order.

Subscribers visiting New York are welcome to use the office, 51 Fifth Avenue, as a temporary address for receiving and forwarding mail, telegrams, or small packages.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, Jan. 12, 1922.

Tenth International Congress of Otology.—The Tenth International Congress of Otology will be held in Paris from July 19 to July 22, 1922, under the patronage of M. Bernard, Minister of Education, and will be presided over by Prof. Pierre Sebileau. Although styled a Congress of Otology, this will be practically one of oto-rhino-laryngology, as the proceedings will cover subjects of interest to those specializing in affections of the ear, nose, and throat. The mornings will be devoted to visiting (under the direction of doctors and interpreters) various hospitals where may be seen oto-rhino-laryngological operations, clinics, and pathological specimens, and also surgery of the head and neck. An exhibition of instruments and anatomical and pathological preparations will be organized at the Faculty of Medicine during the Congress. All communications should be addressed to the General Secretary of the Congress, Dr. A. Hautant, 28 rue Marbeuf VIII, Paris.

Influenza in Great Britain.—Influenza has been prevalent in several of the large towns of Great Britain and especially in London. The disease has been of a mild type and there are some indications that it is subsiding. Steps have been taken by the Ministry of Health to secure special intelligence regarding influenza throughout the country, not merely through the usual channels, but from large employers of labor, and the whole situation is constantly under review, officers with special knowledge being dispatched at once to the scene of outbreak. Speaking generally, the present epidemic has been mild, so much so that hundreds have carried on as usual and have been unaware of slight attacks until they had practically passed. An official of the Ministry of Health, in an interview given to the daily press, said that the epidemic was of a mild type. Deaths in the ninety-six great towns in the week ending Jan. 7, which numbered 418, did not much exceed those of the worst week in the 1920 recrudescence, while the number of cases of pneumonia was very much smaller. Another hopeful feature of the present situation is the comparatively small proportion of deaths in the prime of life, say, at 25 to 45. In the case of the pandemic of 1918 no less than 40 per cent. of the deaths in the autumn were of persons aged from 25 to 45, and in the summer as many as 36 per cent. In the spring of 1920, 35 per cent. of the deaths were in the same age group. In the last two weeks of December 22 per cent. and 26 per cent. respectively of the deaths from influenza were at the age of 25 to 45, a very much smaller proportion. In Sheffield, Rotherham, and some other towns chiefly affected, the disease appeared to be of a mild three-day type—sore throat and severe catarrh, accompanied by discomforts in the nose, have been common. These nasal infections probably account for the neuralgia, persistent cough, and the frequent relapses which are observed in some cases. A large number of patients have had a severe and persistent paralysis

of the lumbar muscles. In some districts this feature has been so marked that an apparent epidemic of lumbago has occurred. At the time of writing, Newcastle-on-Tyne is suffering badly from the epidemic, and business is seriously handicapped. The railway and tramway service is gravely affected. In South Wales 1,000 cases of influenza are reported, and it is stated that the complaint is spreading rapidly.

Sir Sydney Russell Wells a Candidate for Parliament.—As Sir Philip Magnus, who has represented the University of London in Parliament for several years, has intimated that he will not offer himself for re-election another candidate had to be chosen. At a general meeting of the University of London Unionist Association, held last week, Sir Sydney Russell Wells was unanimously selected as a candidate in the Conservative and Unionist interests at the next general election. Sir Sydney Russell Wells is a very distinguished physician and an authority on heart disease who has been vice-chancellor of the university since 1919. He is 53 years of age. He represents the university on the General Medical Council. No better candidate could have been chosen, and it would be a graceful act on the part of the university in recognition of his great devotion to its interests if he were elected without contest.

Section of Surgery, Royal Society of Medicine.—At a meeting of this section, held on Jan. 4 last, Mr. J. P. Lockhart-Mummery read a paper on postoperative embolism and infarction. He said that such cases were divisible into three categories: (1) Those in which death occurred instantaneously, without premonitory symptoms; (2) those with a fatality a few minutes or a few hours after an acute and sudden crisis, followed by dyspnea and pain in the chest; (3) cases in which the patient developed signs of consolidation in the lung following a crisis and recovered. The second class were the more usual cases and here the initial symptoms were acute pain in the chest accompanied by dyspnea. The dyspnea was not due to part of the lung being put out of action, but to the sequential heart strain owing to the limitation of the area of the pulmonary circulation. He, therefore, reasoned that the giving of strychnine in such an event was wrong practice; such stimulants tended to enhance the difficulty of an already strained heart. Effort should rather be directed to relieving the pressure in front of the heart by dilating the vessels there by such substances as nitrite of amyl. After reviewing the pathology, he said that he had arrived at the conclusion that considerable venous stasis was a necessary factor in postoperative thrombosis, but not the only one, as mere recumbency did not suffice to produce it. John Hunter proved that intravascular clotting did not follow the intravenous injection of thrombins, which aided blood coagulation if the blood was in movement. To produce clotting, thrombokinase must be present in the blood. This substance was not found normally in the blood, but was in all the other body tissues, and when a wound was made it was liberated and allowed to enter the blood stream. It sealed up a vessel after a cut had been made into it. Calcium introduced into the blood did not cause it to clot; the amount of that substance normally in the blood was all that was required, therefore any addition to it would decrease its tendency to clot. For thrombosis to occur there must be venous stasis and the presence of thrombokinase; neither alone would bring it about. Therefore, the clot in thrombosis probably formed at the time of the operation or immediately after, and at any period up to some weeks afterward a portion might become detached and cause embolism. Prevention should be the great aim, as when once set up the condition did not lend itself to treatment. The only chance of preventing postoperative thrombosis at present seemed to be by preventing any stasis in branches of the vena cava. Injection of morphine seemed to precipitate it by slowing the circulation, and the more frequent use of morphine in recent years might have something to do with the increase in these accidents. He advocated the doing away with preliminary purgation in operative cases or else confined to six days or more before the operation, and starvation before operation should be entirely discontinued.

Obituary.—A Great British pathologist has passed away recently in the person of Sir German Sims Woodhead, Professor of Pathology in the University of Cambridge. In America, perhaps, Woodhead will be remembered chiefly as the author of a report to a Royal Commission on Tuberculosis, for which he was an investigator. It was shown that bovine tuberculosis can be transmitted to man. In 1892 he was elected Honorary Fellow of the Henry Phipps Institute, Philadelphia, and in 1893 he attended the sixth International Congress on Tuberculosis at Washington, where he exhibited a collection of specimens showing the changes produced by tuberculosis in various organs, both in human and animal subjects. For the collection he was awarded a gold medal by the Congress. In my next letter I shall give some intimate recollections of the late Sir German Woodhead given me by Mrs. Greenfield, the widow of the late celebrated Professor of Pathology at Edinburgh University, whose pupil and assistant Woodhead was, and who was, moreover, a close friend of Prof. Greenfield and family.

1. Observations on the Operative Treatment of Epilepsy, with a Report of Fourteen Cases. John Mason Little.
2. Pyorrhea an Ancient Disease. Carolus M. Cobb.
3. General Physiology in Its Relation to the Problem of New Growths. Frederick H. Pratt.

1. Observations on the Operative Treatment of Epilepsy, with a Report of Fourteen Cases.—John Mason Little takes exception to a paper which has recently appeared criticising the operative treatment of epilepsy, asserts that the benefit sometimes derived from operation has been observed and recorded for a long time, and gives the history of fourteen cases of epilepsy which he has treated by operations on the head. In addition 81 cases are culled from the literature dating back to 1906, making in all 95 cases of epilepsy of all kinds in which some form of operation has given beneficial results in a majority of the cases, and a so-called cure after a considerable interval in a certain percentage. If the cases are excluded in which either extirpation of the cortical center or of tumor was

done the mortality is not high. Little feels that in his cases the operation did no harm. Without exception there was temporary improvement. Some were improved over considerably extended periods of time and there are three which can be called cures over eleven and a half, eleven years and five months, and ten years. Three are relieved and living useful happy lives, nine, six and five years after operation. Some local pathological condition was present in most cases. While not wishing to start the surgeon on a career of indiscriminate operating for epilepsy, Little believes that there is indication that in some cases operation is beneficial.

2. Pyorrhea an Ancient Disease.—Carolus M. Cobb quotes from "Keith's Antiquity of Man" and refers to the LaChapelle man, who is believed to have lived one hundred thousand years ago, to show that pyorrhea is by no means a modern disease. He believes that a disease that began so early and has persisted so long must have a definite cause. The two factors which are common to all the stages of man's development are, first, the teeth have been continuously less used, and have grown smaller and, second, infection. Diet, lack of fresh vegetables, changes in the secretion of the mouth do not explain a disease that has lasted so long. The problem of treatment seems to be the treatment of recurring infection in an organ that is becoming useless. Nature makes no effort to save an organ that is becoming useless or nearly so. If we wish to save our teeth we must bear in mind that they are being less and less used, and that unused or little used organs are prone to infection.

3. Syphilis of the Medium and Smaller Arteries.—Aldred Scott Warthin finds that simple arteriosclerosis (hyaline thickening of the intima) of the medium and smaller arteries is more common in syphilitics than in nonsyphilitics. It is probably not due to the localization of spirochetes in the intima, but is of secondary origin (toxic or mechanical). Syphilitic periarteritis, panarteritis and arteritis obliterans of the smaller arteries occur in all cases of chronic and latent syphilis, in greater or less degree. Syphilitic mesaortitis is essentially a disease of the arterial vasa vasorum. Syphilitic lesions of the smaller arteries are always associated with localization of the infection in any organ or tissue. The lesions are rarely gummatous in character. Syphilitic mesarteritis occurs in the carotids, subclavians, iliacs, femorals, tibial and pulmonary arteries. It is usually of slight degree, and is found only on microscopical examination. Occasionally it expresses itself clinically as aneurysm of these arteries, or in circulatory disturbances due to obstruction of the arterial lumen. Syphilitic obliteration of the pulmonary arteries may lead to the production of Ayerza's disease (chronic cyanosis, polycythemia and splenomegaly). Clinical syphilis of the peripheral arteries of the extremities is more common in the legs and feet, manifesting itself in gangrene, perforating ulcer, sclerosing atrophy, or symmetrical gangrene simulating Raynaud's disease. Syphilitic arteritis may be a cause of peptic ulcer, or pemphigus, localized ulcers, atrophy and various forms of dystrophy, due to disturbed circulation, as the result of partial or complete obstruction of the lumen of the affected artery. Syphilis of the smaller arteries plays a very important part in paresis, tabes, and cerebrospinal syphilis, and in the production of localized degenerations of brain and cord. Syphilis of the coronary arteries is also of clinical importance. In general, it may be stated that localized syphilis of the smallest arterioles is an essential part of the general pathology of chronic or latent syphilis.

10. The Importance of Posture in the Physical Examination of the Heart.—W. Gordon asserts that no cardiac patient has been properly examined who has not been examined, when possible, both in the erect and recumbent positions; and no descriptions of cardiac physical signs can be considered scientific in which the posture of the patient at the time of observation has not been stated. The change from the erect posture to the recumbent produces the following results: (1) Raises and narrows the normal cardiac dulness. (2) Makes the first sound duller and the second sound sharper, so producing the classic "lub-dub." (3) Lessens the anteroposterior diameter of the chest. (4) Almost always markedly narrows the dulness of an enlarged heart, particularly rightwards. (5) Increases the loudness and area of audibility of: (a) Hemic murmurs, both at apex and base, apparently always. (b) Mitral and tricuspid regurgitant murmurs, almost always. (c) Aortic forward murmurs, usually. Some of these murmurs, a, b, and c, may only be audible in the recumbent posture. (6) Lessens the loudness and area of audibility of: (a) The venous hum in the neck in anemia, apparently always. (b) The presystolic murmur of mitral stenosis, usually. (c) The so-called cardiopulmonary or respiratory murmur, usually. Some of these murmurs, a, b, and c, may only be audible in the erect posture. (7) Leaves almost unaffected the murmur of aortic regurgitation. (8) Increases the loudness of the accentuated pulmonary second sound. (9) Makes more marked the reduplication of the reduplicated pulmonary second sound, apparently always. In some cases the reduplication is only heard in the recumbent posture. (10) Causes the partial or complete disappearance of the cardiac dulness in certain cases of cancer (the cardiac sign in cancer.) (11) Causes the apex beat to rise an interspace in some cases of much enlarged heart, or (much rarer) of normal-sized hearts, with abnormally lax supports (cases of cardioptosis). (12) Narrows the dulness of pericardial effusion and resonance in hydropneumopericardium. (13) Changes the distribution of pericardial dulness. (14) Sometimes makes audible a friction sound in pericarditis, not heard in the erect position. (15) Increases the distance at which a distantly heard first sound is audible, as in Graves' disease. In lung diseases the double stethoscope is indispensable, because it can penetrate further than the wooden one and can pick up adventitious sounds which would be missed without it. A double stethoscope helps to determine the presence of mitral systolic murmurs too faint to be sure of with the wooden stethoscope. But (a fact not to be forgotten) a slight aortic regurgitant murmur, distinct to the wooden stethoscope, may actually be inaudible to the double stethoscope. There are some very faint aortic regurgitant murmurs which can only be made sure of by the ear laid directly on the chest.

1. The Prevention of the Development of Rickets in Rats by Sunlight.—G. F. Powers, E. A. Park, P. G. Shipley, E. V. McCollum and Nina Simmonds present this experimental study, the object of which was to determine whether or not sunlight prevents the development of rickets in the rat. A diet was employed which at room light regularly gives rise to a disease in its essential features identical with rickets as seen in human beings. The diet was high in calcium, low in phosphorus, and was insufficiently supplied with fat-soluble A. In other respects it was well constituted. Eighteen rats were placed on the diet. Twelve were exposed to sunlight for a total of 242 hours over a period of sixty-two days. Six were kept under conditions of ordinary room light as control animals. The control rats, killed with ether at the end of sixty days, all showed rickets. The rats exposed to sunlight remained without exception entirely free from rickets. The absence of the lesions of rickets was confirmed by histological examination. The beneficial effect of the sun's rays was not limited to the skeleton, since the condition of the animals underwent a general improvement under the influence of the treatment with sunlight. The exposure to the sun's rays, however, did not entirely compensate for the defects in the diet. The animals remained undersized; the bones though completely calcified remained thin. The writers think it is necessary to conclude that the sunlight in some way raises the efficiency of the body cells. It enables the organism to put into operation regulatory mechanisms which otherwise would have been inoperative or ineffectual. The effects of sunlight and of cod liver oil on the growth and calcification of the skeleton and on the animal as a whole seem to be similar if not identical.

4. Injection of the Bile Ducts with Bismuth Paste, and Observations on the Flow of Bile.—Charles F. Tenney and S. H. Patterson report the case of a man 48 years of age who, following cholecystectomy and the removal of stone from the neck of the gall bladder, made an uneventful recovery except for a biliary fistula. In order to determine the extent of the fistulous tract and its relations to the duodenum, the duodenal tube was passed, and a small amount of milk containing barium was injected into the tube to make clear its outline. At the same time bismuth paste was injected into the external opening of the fistula. A roentgenogram taken immediately after showed the liver ducts extensively injected with bismuth paste. The patient developed jaundice, a rise in temperature and the urine was dark colored and contained a considerable quantity of bile. The mechanical obstruction to the liver lasted about forty-eight hours, after which the patient recovered. Being definitely convinced that no bile was passing into the intestinal canal, a twenty-four hour specimen of bile was collected, and the quantity and rate of flow by various stimuli were estimated. It was found that magnesium sulphate did not increase the rate of flow of the bile, nor did it change in color or consistency, leading one to believe that in other individuals in whom the duodenal tube is used and the bile changes in color and consistency, magnesium sulphate acts only as a stimulant to contractions of the gall-bladder and causes dilatation of the ampulla of Vater, and not as a direct stimulant to the liver, except as the bile in duodenum increases it. The greatest quantity of bile was secreted in the third and fourth hours after meals. Psychic tests showed no immediate change in the flow of bile. One may get normal bile by the use of the duodental tube for diagnostic purposes, even though the patient may have a badly diseased gall-bladder. The entrance of bile into the duodenum definitely increased the flow of bile from the liver. Magnesium sulphate injected into the duodenum which had no connection with the liver, did not increase the flow of bile. Bile injected under the same conditions did increase the flow of bile.

9. The Ovary and the Endocrinologist.—Robert T. Frank refers to experimental work which shows that the corpus luteum contains lipoidal bodies which produce uterine hyperemia and rapid hyperplasia of the musculature and mucosa of this organ. Pharmacological researches show that the follicle as well as the corpus luteum can maintain the growth and nutrition of the uterus. In large dosage hypertrophy of the uterine muscle and mucosa take place. The external genitals and mammary glands are also stimulated. These reactions are specific. Decrease or increase in ovarian secretion can produce clinical symptoms. The present tendency, however, which seeks to include all menorrhagias and metrorrhagias in the functional group is fallacious. Bleeding may be due to systemic causes (heart and pulmonary and kidney diseases), to local inflammations (tubal), and to uterine neoplasms. Hence expert opinion, at times assisted by diagnostic curettage and microscopic examination of curettings, is more often needed than an endocrine prescription. The writer claims that to-day there is no better ovarian extract on the market than in 1910 when he first discussed this subject. The preparations are "defatted" and therefore deprived of such minute doses of the active principle as they may have originally contained. Pharmacologically they are inert. The near future may supply us with at least a partially potent lipoid extract. What is required is purification of the lipoid, a suitable bland menstruum and parenteral exhibition. The action of such an extract will be specific for the genital sphere.

11. Tender Pressure Points with So-Called Symptomless Gallstones.—G. A. Friedman emphasizes two points which he says, although not new, are often ignored in practice, namely: (1) that gallstones are often seemingly symptomless, and (2) that the correct diagnosis of this condition is possible. On pressure tender points in the intercostal spaces at the level of the gall-bladder, in the continuation of the right axillary, scapular, and posterior median line are almost always found in persons suffering from disease of the gall-bladder, even when tenderness in the gall-bladder region cannot be elicited. The presence of these spots is nearly as characteristic as the history in the group of so-called typical cholelithiasis. The writer has been able many times correctly to diagnose cholecystitis as a concomitant condition in otherwise clear cases of gastric ulcer or chronic appendicitis by finding the tender points. The existence of these tender points may be explained by the fact that the infective agent of the gall-bladder has a predilection to settle in small areas of intercostal nerves at the gall-bladder level.

2. The Use of Levulose as a Test for Hepatic Insufficiency.—J. C. Spence and P. C. Brett describe investigations which lead them to conclude that a valuable indication of the efficiency of the liver can be obtained by estimating the changes in the blood sugar concentration, which follow the ingestion of levulose. In a healty adult with a normal liver efficiency, a dose of 50 grams of levulose will produce no appreciable rise in the blood sugar. In a subject with diminished liver efficiency a definite rise in blood sugar will result from the ingestion of levulose. The height and length of the "blood sugar curve" which portrays this rise will be in propor-

tion to the degree of liver inefficiency which is present. The test affords a means of estimating the degree of liver damage in cases of toxic salvarsan hepatitis and other diseases of the liver. The kidney threshhold for levulose is lower than that for glucose and varies in different individuals. The inconstancy of the threshhold for levulose renders the older method of testing liver efficiency by urinary examination inaccurate.

3. On the Tuberculin Treatment of Bronchial Asthma and Hay Fever.—W. Storm Van Leeuwen and H. Varekamp state that in the course of a research on the reactions of normal individuals and patients to intracutaneous injections of various diluted serums, carried out by Landsteiner and themselves, their attention was drawn to the fact that very often persons who show a strong skin reaction after serum injections also give a very marked tuberculin (Pirquet) reaction. This pointed to the possibility of a relationship between the intensity of the Pirquet reaction and the intensity of allergic reactions. With the knowledge that many cases of bronchial asthma must be considered as caused by allergic reactions, it was only a step further to suppose a similar relationship to exist between bronchial asthma and sensitiveness to tuberculin. Other considerations led to the same view. At length, of 34 cases of bronchial asthma which came under their care they started tuberculin treatment in 30 who gave positive Pirquet reaction. Koch's T. O. A. was given subcutaneously—mostly 1 c. c. of a 1:100,000 dilution—which gave no general reaction. The size of the dose was increased with each injection, provided the firmer dose produced no temperature. In nearly all the patients suffering from acute attacks of asthma these attacks disappeared for good after the first two or three injections of tuberculin. In addition the patients were also given protein-free diet and inhalations of benzyl-benzoate. It is not possible to state whether the cures obtained will be lasting. However, the first case in this series was treated fifteen months ago and the last two months ago and thus far there has been but one relapse. The writers do not explain why a hypersensitiveness to tuberculin increases the susceptibility for allergic reactions and why injections of small amounts of tuberculin have a curative effect. Research is being conducted on these points.

4. The Standardization of Suspensions of Red Blood Cells for Wassermann Tests.—Joseph W. Bigger proposes a method for the standardization of suspensions of red blood cells based upon the comparison of the color of the carboxylhemoglobin produced by treating the suspension of red cells with water and passing carbon monoxide gas with that of the standard tube of a clinical hemoglobinometer. The process of preparing this standard suspension is simple and takes only about ten minutes. The method has been tested and found to be accurate.

6. Studies in Milk.—R. Stenhouse Williams reports on some of the work carried out at the National Institute for Research in Dairying which has established certain important facts. First, that the best produced commercial milk can maintain a bacteriological standard of less than 10,000 colonies per 1 c.c. for at least twenty-four hours after milking, even under conditions of cooling and transit which exist in England at the present time. Second, that such milk retains its sweetness at room temperature for a period of time which averages 6.2 days in the winter months and 3.3 in the summer months. Third, that milk of a very high degree of cleanliness can be obtained in an average cowshed if the right worker be employed and be given light, water, steam, and a covered milking bucket. Fourth, that much of the contamination of milk is due to utensils. Fifth, the conditions necessary for the efficient sterilization of dairy utensils, whether by current steam or steam under pressure, have been established.

2. The Radical Abdominal Operation for Carcinoma of the Cervix.—Victor Bonney reviews the results based upon five years' freedom from recurrence. The operation performed has been the most thorough possible, for with the uterus and its appendages have been removed in all the cases the upper half or two-thirds of the vagina, the parametric and paravaginal tissue out to the pelvic side wall and down to the levatores ani and the glands in the obturator fossæ and along the iliac vessels. Every case was operated upon in which there appeared any chance, however small, of removing the growth. The results in this series of cases operated on by the writer between 1907 and 1915 and the first 100 cases operated upon by Comyns Berkeley and the writer between 1907 and 1911, of which operations the writer performed 49, are compared. There is a general similarity between the results of the present and those of the conjoint series, the principal difference being in the number of late recurrences. In both series the seat of early recurrence is usually in the vagina, of late recurrences higher up in the pelvis or abdomen. General cancerous metastasis practically never occurs, but recurrent growth may develop in the bony pelvis, or lumbosacral spine. The important fact is brought out that secondary carcinomatous deposit in the regional glands may exist at the time of the operation, and yet a good result be obtained and that carcinomatosis of the regional glands *per se* does not contraindicate the operation, and as it is impossible except by the microscope to be sure of the condition of the glands, their removal should be part of the routine of the operation in every case. A surgeon undertaking a series of operations performed after the manner that the writer has described elsewhere, may expect, if his operative mortality is the same as that of this series—namely, 20 per cent., that 25 per cent. of the patients originally presenting themselves for treatment unselected, 40 per cent. of those operated upon, and 50 per cent. of those recovering from the operation will be alive and well five years after the operation; he may expect that 5 per cent. of these will succumb from recurrence during the next two years, after which those surviving may practically be reckoned as cured. During this experience the operation mortality dropped from 20 per cent. in the first 100 joint cases to 6 per cent. in the last 50 cases jointly performed. This improvement is attributed to spinal anesthesia, the use of violet green to sterilize the vaginam suturing the vagina, and increased operative dexterity. Until some means of treating operable carcinoma of the cervix is found which will cure more than 35 per cent. of the patients surgical extirpation will remain the proper treatment for operable cases.

6. Pigmentation of the Vermiform Appendix.—E. M. Cowell finds the literature on this subject scant. He says that pigmentation of the appendix has hitherto been regarded as an uncommon condition. Attention having been drawn to it, surgeons will probably be surprised at its frequency. The first specimens were discovered by Mr. W. H. Battle and described by Professor S. G. Shattock in 1916. The condition may be regarded as secondary to changes in the big bowel associated with chronic intestinal stasis. The pigment cells contain melanin and fatty acid substance probably allied chemically to adrenaline. While the exact significance of the pigmentation is not yet clear, it appears constantly in cases of chronic intestinal stasis along with degenerative changes in Auerbach's plexus (associated with a defective mechanism), diminished activity of the intestinal mucosal cells, and lack of the usual protective mechanism against bacterial infection (McCarrison). It is probable that these changes are closely associated with avitaminosis,

since all the pathological conditions already mentioned have been produced experimentally in animals by appropriate diets (McCarrison). From the practical point of view the importance of this conception cannot be overestimated. Chronic intestinal stasis, chronic appendicitis, and many morbid conditions of the cecum may be prevented by the administration of a diet containing sufficient natural foodstuffs which are especially rich in vitamine B.

1. The Early Signs of Disease of the Nervous System. Tom A. Williams.
2. Therapy of Certain Gastrointestinal Diseases. F. W. Foxworthy.
3. Anesthetic Notes. Arthur E. Guedel.

2. Therapy of Certain Gastrointestinal Diseases.—F. W. Foxworthy considers more particularly the treatment of gastric ulcer. When this diagnosis is made the first thing to do is to remove irritants. Mechanical irritation can be relieved by posture. The patient should be encouraged to lie in one position, preferably on the back. An electric heating pad should be placed over the stomach and kept on most of the waking hours. The only contraindication for the pad would be in case of hemorrhage; then the ice-bag can be used or, better, the cold water coil. Formerly gastric lavage was used to a greater or less extent, but the writer's present plan is to use the stomach tube as little as possible, only for sudden emergency or for necessary tests. Medication should be in quantities sufficient to relieve the hyperacidity. Pure sodium bicarbonate, 10 to 60 grains, with an equal quantity of calcined magnesia, may be given. Frequent tests will show the exact number of tests necessary to reduce the hyperacidity to normal. If there is hypersecretion, tincture of belladonna, 10 to 30 drops, can be given from four to six hours apart. If there is a highly nervous state a tablet of luminol may be given morning and evening. In the treatment of recurring or profuse hemorrhage, the ice-bag should be kept over the stomach, morphine sulphate, ⅛ to ¼ of a grain hypodermically, is given from one to three hours apart, according to the severity of the hemorrhage. The patient should not be allowed to move, and the bowels should be moved by enemas. From 5 to 10 c.c. of horse serum should be injected subcutaneously or intravenously, and repeated in twenty-four hours if needed. The alkalies should be increased rather than diminished in hemorrhage, for it has been proven that when the stomach contents are rendered alkaline hemorrhages are not likely to occur. Transfusion may be used as the last resort, but most cases do not require it. An excellent method of administering food during the first week or the entire period of the stay in bed is by means of the Rehfuss tube or the Einhorn duodenal tube. Peptonized milk, 2 ounces, to which 1 ounce of glucose has been added, is administered one or two hours apart. The patient is allowed to have water, but this is the only thing allowed in the stomach except the medication. If for any reason the tube is not used, Sippy's milk and cream method should be used. At the end of the first week, and in severe cases at the end of the second week, thoroughly cooked rice, tapioca, or potato soup are added to the diet. At the end of the fourth week solid food may be added. Foods to be avoided are meats, meat broths, meat gravies and sauces, stimulants, acid fruits and vegetables, sweets and coarse, irritating foods. If the patient gets along nicely meats may be added after several months.

4. Work of the Cardiac Clinic at the Cumberland Street Hospital.—Albert Comstock describes the method of handling patients and keeping recording data in use at this clinic, and lays great stress on the functional test of cardiac efficiency. At present a test is used which he says is probably inferior in many respects to the J. C. Schneider one used at Mitchell field, and yet the classification of cases they make seems so far to have checked up with remarkable accuracy with the other data, and with the prognosis they have based upon it. The patient sits quietly for some minutes, until the pulse counted twenty seconds, for three alternate intervals is equal, and then the pulse, respiration, and systolic and diastolic pressures are noted. The patient then undergoes exercise to dyspnea. Stationary running is used. The writer does not believe in the so-called "standard exercise," as they are dealing with patients most of whom have very little cardiac reserve, and in whom attempts to standardize exertion might readily produce dangerous results. When one has produced dyspnea in such a case he has called into play what reserve he may have, and that condition is the basis of the test. Immediately after exercise the systolic and diastolic pressures are taken, as well as the pulse and respiration. They are taken at five minute intervals for twenty minutes. Based on the results it is found that cases may readily be typed into four different classes, as follows: (1) The systolic pressure rises five or more millimeters, and slowly within twenty minutes returns to normal, but not below. This class of cases will show a rise of pulse not more than ten beats. Whatever the lesion the cases in this class may be given a good prognosis, provided they can be properly cared for. (2) A rise of blood pressure occurs, but the pressure after a shorter period of maintenance will fall below where it started. This shows some reserve, but a weakened myocardial state, as evidenced by the exhaustion fall. This class of patients inevitably show dyspnea on moderate exertion, and often some edema. Their prognosis is fair, but their reserve must be carefully conserved. This class of patients usually shows a pulse rise of more than ten. (3) The pressure does not rise more than three millimeters, if at all, and immediately falls to below the starting point. These cases have practically no reserve and must be rated and handled accordingly. A very pronounced pulse rise occurs. (4) Here an immediate drop occurs, and dyspnea is almost immediate. These patients have no reserve; they require no test, nor is it safe to give it. In all cases in which unexplained tachycardia or dyspnea are present and in which tremor or nervous tension are seen the Goetsch test is done to detect cases of hyperthyroidism. They are beginning to eliminate from their nosology the term "decompensation," and to encourage in its place merely a statement as to the amount of cardiac reserve present. To the writer's mind the heart which shows the slightest deviation from normal is not compensating. When any dyspnea or lowering of the reserve index is present the patient is decompensating. What is commonly called decompensation is one of three conditions—auricular fibrillation, auricular flutter, or dilatation. Another disease which is eliminated from their nomenclature is "angina pectoris." The drug therapy used in the clinic is very simple; digitalis, nitroglycerin, aconite, and the bromides, together with castor oil, are the main remedies.

6. A Case with High Creatinine Retention and a Post Puerperal Psychosis.—J. F. W. Meagher reports this case, in which the blood chemistry examination a few days after delivery showed creatinine 6.6 and 6.8, also a moderate urea retention and a hyperglycemia. Myers and other investigators have shown that a high creatinine retention portends a grave outlook. This woman recovered physically. The urine, which showed a great amount of albumin and hyaline casts, cleared up rapidly, showing that one might at times fail to find a nephritis if he relies on the urinary findings alone. Associated with the kidney trouble was a mental condition thought to be an infection-exhaustion psychosis. In such a condition one ordinarily gives a good prognosis, but in this case as time went on there were elements suggestive of dementia praecox and the outlook for recoevery at the end of three months was dubious.

2. The Effect of Treatment for Syphilis on Severe Anemias.—H. O. Foucar and John H. Stokes find that severe anemia, either primary or secondary, associated with late or latent syphilis, is apparently rare, twenty-five cases appearing in approximately 4800 records in the Section of Dermatology and Syphilology of the Mayo Clinic. Pernicious anemia may be seen in association with syphilis, but no case exhibiting an incontestable etiological connection has appeared in their records. Pernicious anemia in the apparent absence of syphilis may yield a positive serum Wassermann reaction. Mercury by inunction, used alone, produced an unfavorable reaction in four of nine patients with anemias who had previously improved under arsphenamine, but all had primary anemia and subsequently showed evidences of a relapsing unfavorable course. It seems, therefore, that in syphilis with anemia mercury should be used with caution, especially if the picture suggests the primary type. Only one of twelve patients with secondary anemia became worse under arsphenamine. Arsphenamine has been much more effective in secondary than in primary anemia, but curiously disappointing in secondary anemia with associated manifestations of syphilis. Twelve of sixteen patients improved under transfusion, four of them after arsphenamine had failed. In four of sixteen cases transfusion was without effect. Transfusion should be a preliminary to arsphenamine when the hemoglobin is below 20 per cent. Reactions to arsphenamine injections must be carefully avoided since they may produce an alarming drop in hemoglobin. No satisfactory rule for determining which case would improve on treatment for syphilis and which case would not could be arrived at. In general half the cases may be expected to improve. The degree of improvement is not necessarily proportional to the demonstrability of syphilis. The pernicious anemia associated with undoubted syphilis has run the ultimate course of pernicious anemia, regardless of the treatment for syphilis. Hemoglobin estimations alone are not sufficient to indicate the progress of the patient. The hemoglobin may rise and the number of erythrocytes fall at the same time. Arsphenamine treatment is safe if carefully used in anemia, and should be employed in patients with undoubted evidence of the disease, and, as a therapeutic test, when reasonable suspicion of its presence exists. Transfusion must remain the ultimate resort in primary cases, and in those cases associated with syphilis in which arsphenamine has failed, even in the presence of syphilis, the best effect will be secured by both together.

5. Balantidium Coli and Pernicious Anemia: Report of Four Cases.—A. H. Logan points out that the clinical symptoms of invasion by *Balantidium coli* bear a great similarity to those produced by ameba. Both present an acute and a chronic form. In the acute form there is severe bloody dysentery, with great loss of fluid and marked tonicity. Perforation may occur. Death follows usually in from a few days to a week or two. The chronic form often exists for years with alternating constipation and diarrhea. In the chronic type the prognosis is bad only when the syndrome of pernicious anemia is added. In the cases reported death has been due to pernicious anemia rather than directly to the dysentery. It seems probable that the constant subjection of the blood-forming organs to the poison is the cause of the pernicious anemia syndrome in the chronic type of case. In his latest case of *Balantidium coli* infection the writer has employed arsphenamine with apparently good results. On account of encystment treatment must be carried out for a long time. It is interesting in connection with the family histories of three of the cases reported that death of one or more parents, brothers or sisters, persons in the same household, living under the same conditions, and eating the same food, occurred from pernicious anemia or anemia. This infection may explain the family tendency to pernicious anemia in many cases.

6. Some Experiences with the Meltzer-Lyon Method of Draining the Biliary System.—Anthony Bassler, William Henry Leckett, and J. Raymond Lutz, during the past year, have been conducting investigations with clinical cases, operation observations and animal experimentation pertaining to the Meltzer-Lyon method of aspirating duodenal contents after the installation of a solution of magnesium sulphate. As a result of their observations they feel that the following conclusions are warranted: (1) The assumption of Meltzer of "the law of contrary innervation" is not proved, and this throws into doubt any specific effect of relaxation of the sphincter of Odii and contraction of the gall-bladder induced by a magnesium sulphate solution. (2) Any one of many substances taken into the stomach or injected into the duodenum will cause a ready flow of bile, of which a solution of hydrochloric acid in about one-third the acidity of normal gastric juice is the most potent for discharge of bile in large quantities and obtaining characteristic "B" bile. (3) That the deeper color of the "B" bile is due to oxidation and not concentration from retention in the gall-bladder, this bile most often coming directly from the liver as a phenomenon of bile secretion. (4) That the viscosity of bile does not elevate its specific gravity to any practical extent. (5) That the margin of error in deducting from the presence of mucopurulent flakes, pus cells, inflammatory débris, bacteria and cells in the aspriated bile as positively coming from the gall-bladder is too great for clinical deduction. (6) That the physiology of the gall-bladder should not be deduced from anatomy and relationship alone—that its most important function seems to be to relieve pressure within the biliary system to protect the pancreas rather than acting as a reservoir for bile in a digestive sense and that the physiology of bile secretion and gall-bladder function should be studied more thoroughly. (7) That cholectomized individuals show the characteristic "B" bile even shortly after operation before the ducts have had a chance to dilate. This occurs so commonly that "B" bile cannot always be from the gall-bladder. (8) The increase in specific gravity in aspirated bile by this method is due to the content of magnesium sulphate which appears to be resorbed into the portal circulation and is excreted by the liver substance in the bile. It is erroneous to deduce clinically in both amounts of bile obtained of any gradation (A, B, C, D) or by specific gravity estimations as to whether bile stasis exists or not. (9) That where true pathology exists in the gall-bladder the method is a poor substitute for proper surgery. It may be employed in suitable cases as a temporizing means, but it should not be depended upon to correct or definitely benefit pathologically diseased gall-bladders or when gallstones exist.

8. Immune Bodies in Type I Lobar Pneumonia.—Edward Steinfield and Herbert J. Darmstadter removed blood from a male patient suffering with Type I pneumococcus pneumonia on the fourth day after the injection of immune serum, and conducted agglutination tests by the macroscopical method. This consisted in mixing in small test tubes 0.5 c.c. of a twenty-four-hour broth culture of pneumococcus Type I and 0.5 c.c. of the patient's serum in various dilutions, the final dilution being of course double that of the strength of the serum used. The test tubes were then incubated at 37.5° C. for one hour, placed in the refrigerator for

twenty-four hours, and read for clumping. The patient's serum showed definite power of agglutination in dilutions up to 1 to 10 (the final dilution). There were sufficient immune bodies in the patient's serum to protect against 500 times a lethal dose of Type I pneumococci. Controls of normal serum did not protect against the lowest dose.

11. An Auscultatory Sign Observed in Acute Abdominal Diseases.—Paul W. Aschner has applied auscultation to the abdomen in acute cases and finds that the heart sounds and the inspiratory murmur are audible over three or four of the quadrants in a large proportion of cases. The heart sounds are somewhat distant and remind one of the fetal heart sounds familiar to the obstetrician. The inspiratory murmur was audible at times with quiet respiration, and at others only when the patient was requested to breathe more deeply. When the abdomen was opened the peritoneal cavity of patients presenting these ausculatory signs was found to contain free pus, seropurulent fluid or blood (as in a case of ruptured tubal pregnancy). Several cases of ascites were examined with reference to this sign and were negative in every instance.

12. A Contribution to the Study of Lethargic Encephalitis in Its Relation to Poliomyelitis.—M. Neustaedter, John H. Larkin, and E. J. Banzhaf describe experiments showing that five monkeys were completely protected from poliomyelitis by sera of patients convalescent from four undoubted cases of lethargic encephalitis and one suspected case. Their results compare favorably with the results of other investigators in the neutralization experiments of poliomyelitis virus and convalescent human poliomyelitis sera.

Large Doses of Arsenic in the Treatment of Nervous and Mental Diseases.—Bianchi of the Neurological Clinic of the University of Parma refers to the use some years ago of sodium cacodylate in Parkinson's disease and certain other spastic and rigid states. Incidentally in high blood pressure cases the latter was reduced. Some patients benefited were hemiplegics in whom the contractures were favorably influenced and presumably the high blood pressure which preceded the stroke. Results of this type naturally raised the question "were these beneficiaries also syphilitic?" The cacodylate was given by ordinary hypodermic and the daily quantity given ranged from 40 cgms. to 2 grams, beginning with the small dose. Other conditions treated in this manner were purely functional—depressive states and neurasthenia. The experience in the Parma Clinic seems to have been striking, although of short duration after withdrawing the remedy. The conditions treated were cases of cerebral palsy in relatively young subjects associated with paralyses and contractures and in some cases with epilepsy. The spasticity showed improvement and the blood pressure came down. The patients in this group all showed mental defect and some also presented athetosis and choreiform movements, and the latter motor disturbances showed improvement. The amount of improvement seemed all that could have been possible under the circumstances for the arsenic was pushed to the limit. Recently in the French clinics the same drug has been given intravenously for true Parkinson's disease as well as the spurious form which follows epidemic encephalitis with considerable success. This resource has also been tested in the Parma Clinic. Here, as in the preceding cases, there was some improvement and the author will investigate further. A case of paresis treated intensively with the cacodylate showed no change.

Schweizerische medizinische Wochenschrift.

December 15, 1921, li, 50.

Tuberculous Myocarditis.—This subject is discussed in two consecutive papers, of which the first is by Massini of Professor Stahelin's Medical Clinic at Basle, while the author of the second is Lüscher, assistant to Professor Hedinger of the Pathological Institute of the same city. Of recent years evidence has accumulated of the existence of nonspecific inflammation of tuberculous origin. The most familiar type is lupus erythematosus of the skin. Of the same nature are forms of cirrhosis of the liver, contracting kidneys, etc. The nonspecific inflammation is often associated with active tuberculosis of the lungs, etc. In other words, tuberculosis may be said to imitate many nonspecific lesions. Often the nature of some of these is in doubt, as in so-called tuberculous rheumatism of Poncet. In some cases a few bacilli may be found, although naturally there are no tuberculous histological changes. In other cases with no trace of bacilli in the actual lesions toxins generated elsewhere are accused of inciting the inflammation. We know little of the nature of chronic myocarditis, and while actual bacillosis of the myocardium is also known the frequency of simple myocarditis in the tuberculosis is beyond doubt. In Poncet's conception of a tuberculous type of rheumatism myocardial lesions are assumed. A common sense view of these cases would make myocarditis of the tuberculous due to an associated infection. However, the author has a case in which tubercle bacilli were actually found in the myocardium of a woman aged sixty-eight, in which the full autopsy diagnosis was chronic fibrous myocarditis without evidence of any active tuberculous lesions in the body, other changes being those of vascular degeneration, chronic bronchitis with emphysema and indifferent lesions. Apparently the bacilli were equal to the task of setting up simple myocarditis. In the Lüscher paper the author deals with one case of actual tuberculosis of the myocardium, in which there is a production of specific granulation tissue as well as the presence of bacilli. This tissue has a certain tendency to fibrous metamorphosis. The author gives two cases in great detail. It does not appear that either patient was tuberculous elsewhere. The second patient of Lüscher's was apparently more closely related to Massini's case than to his first one. That is, there was no specific tissue characteristic of tuberculosis and the case would ordinarily have passed for nonspecific.

Gazette des Hôpitaux.

December 13-15, 1921, xciv, 98.

Stomach Vertigo and Extrasystoles.—Lemierre refers to Trousseau's description of *vertigo a stomacho laeso* and to the popular association of dizziness with indigestion. Apparently the great clinician was unable to relieve this kind of vertigo by treating the stomach, nor does it appear that he gave these patients a thorough examination. He doubtless knew of auricular vertigo, but he could hardly have been aware of the Stokes-Adams syndrome; at any rate, he does not mention the state of the pulse of these subjects. In the elderly, gastric vertigo was apt to be of bad prognostic, as it was frequently followed by apoplexy or softening of the brain. In stomach vertigo, according to Trousseau, the digestion might be excellent. At the present day the clinician thinks of the stomach only after all other causes of vertigo have been eliminated—the ear, circulation, and nervous system. The author has often seen cases of alleged stomach vertigo which were found to be due to Stokes-Adams syndrome, labyrinthine disturbances, arteriosclerosis, brain-tumor, etc. He has never seen a case, in fact, which answered to Trousseau's type of vertigo, but believes that this occurs albeit very rarely. The so-called gastric vertigo is probably a condition due to air swallowing and accompanied by extrasystoles, for in subjects with this syndrome we see slight vertigo and fainting fits attributable to an intermittent ischemia of the bulb, the mechanism being identical with that of the Stokes-Adams syndrome. The dyspeptic with extrasystole is a neurotic subject without organic stomach disease. The author gives a long case history of a patient with syncopal attacks provoked by extrasystoles which yielded to simple dietetic precautions maintained over a year, chiefly small and nutritious meals. His cardiac rhythm became normal after years of irregularity. As the patient was 80 years old and an ex-syphilitic with an apparently incurable indigestion, the author naturally regards this result as almost unique. Vertigo and syncope have probably an analogous mechanism in these cases, to wit, one involving the vagus nerve and the circulation of the bulb.

Book Reviews.

SOAPS AND PROTEINS, THEIR COLLOID CHEMISTRY IN THEORY AND PRACTICE. By MARTIN H. FISCHER, Doctor of Medicine, Eichberg Professor of Physiology in the University of Cincinnati. Price $4.00. New York: John Wiley & Sons, 1921.

WHEN the versatile author began his studies of soaps, his aims were purely biological—a study of a phase of colloid chemistry, in which soaps may to a certain extent replace proteins. From the study of soaps it then became possible to extend the research to proteins. On the one hand the work could be further extended to soap manufacture, while at the other extreme the studies of protein culminated naturally in the behavior of the animal cell in such diverse conditions as coagulation, digestion, and intoxication with ammonia and the heavy metals. As the author states, the subject matter of the book was dictated largely by circumstances, and it therefore has an appeal to very different classes of students—chemists of all kinds, biologists, and physiologists, and the commercial soap manufacturer.

DIE GESCHLECHTSKÄLTE DER FRAU, Eine Psychopathologies des Weiblichen Liebesleben. Von Dr. WILHELM STEKEL. Nervenarzt in Wien. Zweite, verbesserte und vermehrte Auflage. Preis M 96. Berlin and Vienna: Urban & Schwarzenberg, 1921.

THE first edition of this work appeared in 1920 and the present one contains eighty-eight additional pages. The first edition of so important a monngraph was quickly exhausted, and in the meantime the author did his best to incorporate overlooked and new matter. A chapter has been added on the climacteric years. The prodigious literary activity of the author is shown in the fact that this monograph of nearly 500 pages—easily the "headquarters" of the study of feminine frigidity—is only one of a series of works by the author in the general province of what he terms "parapathic affections" or "disorders of instinctive and affective life." The other volumes of the author's series, some of which are as yet unissued, comprise nervous anxious states, onanism and homosexuality, psychic male impotence, psychosexual infantilism, masochism and sadism, compulsive neuroses and epilepsy. There will also be a terminal volume which covers the technique of psychotherapy and contains a general index and summary. When this series is completed the author will stand out as an encyclopedist in his wide province, who has produced his system without the aid of collaborators. It is extremely unusual, if not altogether unique in our day, for one man to assume the entire responsibility for a medical system of eleven volumes of published material. To find its fellow we have to go back to medieval writers.

SOCIAL ASPECTS OF THE TREATMENT OF THE INSANE. By JACOB GOLDBERG, Ph.D. New York: Columbia University Press, 1921.

THIS volume on insanity, evidently from the pen of a layman, constitutes number 2 of volume xcvii (whole number 221) of the series known as "Studies in History, Economics and Public Law" of Columbia University, published by the Faculty of Political Science of the same. The work was composed because the author was unable to find any volume which covered the subject matter. The six chapters deal in succession with the history of care of the insane in New York State, insanity as a community problem, results of State Hospital care, a social survey of 786 admissions to State hospitals, social treatment of the insane and recommendations and conclusions. The material considered is largely Hebrew insanity, not from choice, but because the writer, himself of this race, moved along the lines of least resistance, having a greater degree of access to the documents. It is perhaps hardly fair to allude to the author as a layman, for while he is not an alienist or lawyer specializing in forensic cases, nor a professed psychologist, nor pedagogue, he approaches the problem of insanity from the angle of sociology and economics and is therefore able to qualify as an expert. Another modern discipline which bears notably on his presentation of the subject of insanity is that of mental hygiene, an outgrowth of the community plan of preventing insanity. The book abounds in footnote citations of passages from alienists, hospital reports, judicial decisions, writers on delinquency, sociologists, statisticians, mental hygienists, writers on adolescence, etc., and furnishes an excellent general introduction to the subject of insanity, and a work of authority on insanity among the Hebrews.

MENTAL HOSPITAL MANUAL. By JOHN MACARTHUR, M.R.C.S., L.R.C.P. Senior Assistant Medical Officer, London County Mental Hospital; Colney Hatch; Lecturer on Mental Diseases to the North-East London Post-Graduate College. New York: Oxford University Press, American Branch, 1921.

THIS volume deals with the following subjects: The mental hospital, the assistant medical officer, treatment of the insane, emergencies, treatment of special mental states, defective habits, admission of new cases, recoveries, contagious diseases, reception of patients and statutes relating to the insane. There is no chapter on insanity as a community problem, and in his preface the author states expressly that the book is for intramural activities alone. Preventive as well as follow-up efforts are not touched on. Although intended as a handbook for those who have already elected to serve in mental hospitals it strikes us that it would serve excellently as a textbook or for collateral reading during the last school year. In most colleges the student learns what he knows of insanity from his forensic textbooks and those on diseases of the mind and nervous system—neither of which superposes what might be learned from a book of this scope.

ESSENTIALS OF DIETETICS. A Textbook for Nurses. By MAUDE A. PERRY, B.S. Formerly Dietetitian and Instructor in Dietetics at Michael Reese Hospital, Chicago, etc., etc. St. Louis: C. V. Mosby Company, 1918.

THIS small volume contains 159 pages and is divided into two sections, devoted respectively to essentials of dietetics and diet in disease. It is composed along conventional lines although under diet and disease there is a doubling up of subjects which saves a certain amount of repetition. Thus the diet of renal and cardiac disease is given jointly, as is that of anemia and tuberculosis, skin diseases and scurvy, and affections of the liver and metabolic anomalies—with the exception, of course, of diabetes which has a separate chapter. This grouping in no wise implies that the diet for skin diseases corresponds to that of scurvy, for each is separately dealt with. The author, however, seems to see a marked factor of undernutrition in skin diseases. But it is more practicable to think of a greater part of skin diseases as allied with metabolic disturbances, like gout, obesity and diabetes, rather than with undernutrition. Again, the diet of acne agrees closely with that of atonic dyspepsia, etc.

THE CLINICAL EXAMINATION OF DISEASES OF THE LUNGS. By E. M. BROCKBANK, M.D., F.R.C.P., and ALBERT RAMSBOTHAM, M.D., F.R.C.P. Price $1.50. New York: Paul B. Hoeber, 1921.

BOTH authors are members of the faculty of the University of Manchester (the former being the Dean) and both are internists in the Royal Infirmary. The booklet of nearly a hundred pages dispenses entirely with radiographic diagnosis and its seven chapters are devoted respectively to preliminary considerations, routine examination, inspection, palpation, percussion, auscultation and physical signs. The work is wholly personal to the authors and the outgrowth of the experience of teachers on the subject concerned. It is also an indorsement of the success of a similar book on the heart. It is written entirely for the student although not advertised as a mere quiz compend or guide to examinations.

BIDRAG TIL HJERNECHIRURGIENS KLINIK OG RESULTATER. Av V. MAGNUS. Kristiania: Trykt i Merkur, 1921.

THIS brochure of 138 pages is devoted to the indications and technique of surgical intervention in brain tumors, the surgical treatment of trifacial neuralgia, the technique of extirpation of the Gasserian ganglion and palliative trepanation. The book contains 111 case histories and brief conclusions therefrom.

ANXIETY HYSTERIA. By C. H. L. RIXON, M.R.C.S., Senior Neurologist, Ministry of Pensions' Neurological Hospital, Exeter, and D. MATTHEW, Neurologist to the Same Institution. Price $1.50. New York: Paul B. Hoeber, 1921.

READERS of Freud and Stekel are doubtless familiar with the conception of anxiety-hysteria, which is the subject of the present monograph. Chapters are given on the nosological position, psychopathology, symptoms, diagnosis, and treatment and there is a special one on the conversion symptoms of hysteria. The very largely military character of the material appears to eliminate the necessity of sex mechanisms in bringing about mental conflicts. It is for this reason that the authors seek to rid themselves of the term and suggestion of "psychoanalysis" and to substitute that of "mental exploration." Civil life shows plenty of like cases without the sex element. There is a foreword by Dr. Lisle Webb, the head of the Pensions' Military Hospitals. The reader is informed that the term "anxiety hysteria" is largely synonymous with functional neuroses, comprising much that goes by the name of neurasthenia, shell shock, and hysteria. The authors, however, recognize a true neurasthenic syndrome and a psychasthenia which comprises phobias and obsessions.

NERVÖSE ANGSTZUSTÄNDE UND IHRE BEHANDLUNG. Von WILHELM STEKEL, Nervenarzt in Wien. Dritte, vermehrte and verbesserte Auflage. Price 78 Marks. Berlin and Vienna: Urban & Schwarzenberg, 1921.

THIS work appeared originally in 1908 with a preface by Freud. From the first the author has sought to change the nomenclature of the neuroses by eliminating such names and concepts as neurasthenia and psychasthenia, while hysteria is reduced to conversion phenomena and hysterical fear states, in which conversions to physical phenomena also occur. For the older concepts he substitutes anxiety neuroses and parapathies.

He divides his subject matter into two principal sections—anxious neuroses and phobias. The former differ from the latter radically in that the morbidity is objective and physical while the phobias are essentially subjective and affect the behavior. Anxiety neuroses therefore are always mimicking organic disease and are always motivated by a mental conflict.

Stekel gives the impression that he is the chief pupil and logical heir of Freud. Originally a follower he now claims to be a leader and asserts that he has won Freud over to the acceptance of some, at least, of his views, while in others he is at variance with his master. The author laments that the specialist loses touch with ordinary practice because he naturally gets only the worst types of psychogenic disease pictures. The family physician could doubtless greatly benefit his patients by a study of the modern theory and practice of neuroses.

HANDBOOK OF ELECTROTHERAPY FOR PRACTITIONERS AND STUDENTS. By BURTON BAKER GROVER, M.D., President of the Western Electrotherapeutic Association; Fellow of the American Electrotherapeutic Association, etc., etc. Price $4.00 Philadelphia: F. A. Davis Company, 1921.

IN his preface the author estimates that about 25,000 physicians in the United States employ electricity as a therapeutic agent, and that few of the medical schools give systematic instruction in electrotherapy. This he regards as sufficient justification for the publication of a new textbook giving the greatest amount of instruction in essentials in the least space. The book contains 417 pages and 103 text illustrations exclusive of six plates of twelve charts. With the exception of a chapter on röntgenology the work is devoted wholly to the application of electric currents. There are three chapters devoted to electrophysics and electrochemistry, one to galvanism and static currents jointly, one to high frequency and sinusoidal currents jointly, and one to diathermy. Faradism is considered briefly under galvanism. Diseases in which electricity is indicated are comprised under blood pressure, hyperpiesia, pain, genitourinary diseases, and miscellaneous in which all other indications for electrotherapy are alphabetically summed up. The arrangement is therefore eminently practical. Intentionally or unintentionally the author does not invade the domain of the neurologist, save, of course, in the relief of pain. He is thus able to reduce the size and cost of the book and at the same time draw a sharp line between general electrotherapy and neurology. Thus the entire subject of electrodiagnosis occupies but two pages.

FEEBLENESS OF GROWTH AND CONGENITAL DWARFISM With Special Reference to Dysostosis Cleidocranialis. By Dr. MURK JANSEN, O.B.E., Lecturer on Orthopedic Surgery, University of Leiden, Holland. New York: Oxford University Press, American Branch, 1921.

THE author seeks to work out the following two principles: First, injurious agents affecting growing cell groups enfeeble their power of growth; second, the measure in which growth is enfeebled is proportioned to the rapidity of growth. The first section of the book is devoted to feebleness of growth, its tissue and organ expressions, including and outside of the locomotor apparatus; while the second section is taken up with the various forms of dwarfism (exclusive of true nanism) with special references to cleidocranial dysostosis. In his preface Dr. Robert Jones classes the volume as a contribution to philosophy by a humanitarian orthopedic surgeon.

THAT BOGEY MAN THE JEW. By G. FRANK LYDSTON, M.D., D.C.L., formerly of the Faculty of the State University of Illinois, and of the Chicago Kent College of Law. Containing 136 pages. Price $1.25 net. Kansas City, Mo.: Burton Publishing Company.

THIS little book is a reply to an article entitled "The International Jew" which appeared recently in the *Dearborn Independent*. The author states that he was impelled to write it merely because taking up the gauntlet in behalf of the fellow who is receiving the punches is a sort of psychic habit into which he has fallen. He has not only taken up the gauntlet but has used it unsparingly, rather indiscriminately, sometimes even venomously, not alone on the "Jew-baiter" but on any human frailty that has chanced within striking distance. The Treaty of Versailles, militarism, democracy, etc., all come in for a share of hard knocks. That the book will accomplish the author's aim of promoting a better understanding between Jew and Gentile is perhaps doubtful, but it affords an hour's reading and a little study of human nature that, to say the least, is not dull.

READINGS IN EVOLUTION, GENETICS, EUGENICS. By HORATIO HACKETT NEWMAN, Professor of Zoology in the University of Chicago. Price, net, $3.75. The University of Chicago Press, Chicago, Ill.

FOR a work handling such difficult subjects this book proves to be remarkably interesting as well as thoroughly instructive. It brings under one cover a collection of excerpts wisely chosen, beautifully classified, and written by the keenest minds devoted to the offered knowledge.

The book is divided into five parts. Part one gives an outline of the history of the development of evolutionary science with the names and contributions of the leading evolutionists. Part two offers the evidences of organic evolution. Part three treats with causo-mechanical theories of evolution using Darwin as the main topic. Part four is devoted to genetics or modern experimental evolution. Part five takes up eugenics —genetics working out human improvement. This outline of the book sounds a little dry, but it belies its subjects, for the book itself is a fascinating presentation of vital material all devoted to the ultimate development of a race which can be free of unnecessary blemish to carry forward the work of the world in happiness and health. In other words it is a splendid working out of the survival of the fittest of the best species—sound mentally, morally, and spiritually. It does not seem too much to hope for in the time to come, when the knowledge offered in this book shall have been combined with other efforts for betterment of mankind. Only mankind is so slow.

The publishers as well as the author deserve high commendation for the beauty of this publication. The type is delightful and illustrations are cleverly reproduced.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held December 15, 1921.

THE PRESIDENT, DR. GEORGE DAVID STEWART, IN THE CHAIR.

THE program of the evening was arranged in co-operation with the Section on Genitourinary Surgery.

Renal Infections.—Dr. WILLIAM C. QUIMBY of Boston read this paper, which was based upon experimental work carried out in the Laboratory of Surgical Research of Harvard Medical College and observations made in the clinic of the Peter Bent Brigham Hospital. He stated that for many years it had been generally appreciated that two outstanding and evident routes existed by which it was possible for infectious organisms to reach the kidney, namely, by way of the blood stream and upward through the urinary passages. The first was called the descending, the second the ascending route of infection. It came to be known that virulent living organisms might and frequently did pass through the kidneys, and as frequently left it intact. This property of the kidney was a basic one, holding true for all bacteria as well as for inert particles of matter, if these were of a size sufficiently small. If the kidney was able to transmit organisms without demonstrable detriment to itself it became necessary to look further for the reason why it might become the seat of inflammation often leading to the serious crippling of its function or to complete destruction. The two outstanding reasons were evident. The first concerned the virulence and quantity of the infecting organism; the second was found in stases within the organ itself. There was, however, a very definite and rather low limit in the numbers of bacteria which could thus be gotten rid of. Organisms of higher virulence and in large numbers on reaching the kidney by way of the blood stream could not be gotten rid of but remained to cause infection. This infection clinically was of various degrees of severity. A second potent contributing cause of infection of the kidney was found in any circumstances which slowed down the mechanism by which the kidney rid itself of its product, the urine, and thus brought about stasis of greater or lesser degree. Impediments to the kidney mechanism came most frequently from stone, ureteral angulations due to ptosis, tumors, and anomalies of the renal blood vessels. Infection which reached the kidney by the blood stream was transmitted to the blood from some pre-existing focus, so attention should be paid to finding such localization in teeth, tonsils, bowels, etc., and removing them. That infection should reach the kidney by ascent from below presupposed of course the existence of cystitis. Knowing, as we did today, the remarkable resistance of the bladder mucosa to infection under ordinary conditions, it became at once evident that the view which held the source of infection of the kidney to be by way of the blood stream must be true in the large majority of cases. Circumstances occurred, however, notably in diseases of the lower urinary tract, such as stricture, prostatitis, enlargement of the prostate in men and cystocele in women, which led to frequent infections of the bladder. The problem then concerned those conditions which might or might not permit the upward propagation of bacteria from bladder to kidney. There were two ways by which bacteria from the bladder might reach the kidney, one by way of the lymphatics and the other by the lumen of the tube. The first had never been satisfactorily proven. None of the work along this line bore careful criticism. The objection urged to infection by way of the lumen was that because of the current of urine, as well as contracting muscular peristalsis, bacteria did not have sufficient power of motion to ascend. This objection was entirely valid. Only where the ureterovesical valve had become incompetent and the ureter a dilated tube with indurated wall could there be an approach to conditions which would permit such an ascent of bacteria. There was still another method of infection of the kidney which had not received sufficient consideration either by physiologists or clinicians, namely, the so-called *ureteral reflux*. This was distinctly *not* a retroperistalsis, as had been shown by Penfield. (*American Journal of the Medical Sciences*, July, 1920). Dr. Quimby described these experiments and also those of Graves, whose experiments on rabbits and dogs showed that while reflux occurred at widely differing degrees of intravesical pressure, a quick elevation of this pressure was more potent in promoting this reflux than a slow one. Having shown that this reflux occurred in animals, it became of interest to determine whether it was a phenomenon entirely confined to laboratory animals, as the rabbit, or whether it could be produced or observed to occur spontaneously in man. They had been attempting to produce the reflux in suitable patients by introducing into the bladder a solution of bromide of sodium, while observing at the same time the ureters by means of the fluoroscope. In somewhat over half their observations it had been possible to see a column of opaque solution suddenly penetrate one or both ureters. In a number of normal individuals, after filling the bladder to examine its outline by *x*-ray, the plates were found to show that the injected fluid had penetrated upward into either one or both ureters. The importance of this reflux, if it proved to be as common a phenomenon as now seemed to be the case, was great for the problem of the ascending route of renal infection. Clinical experience brought evidence which made the activity of the reflux a fair presumption. First, the so-called catheter or ureteral chill supported this thesis. The catheter or ureteral chill was probably explained by assuming that a bladder, for some reason more irritable and hypertonic than normal, had been stimulated to contract suddenly by the passage of the instrument and a reflux of a portion of its infected contents upward into the kidneys was thus brought to pass. Once having reached the kidneys, this material found ready access to the circulation, as experimental work had shown. A second clinical phenomenon, only logically explained by the operation of ureteral reflux, was that during convalescence following prostatectomy a patient might suffer sharp rise in temperature, sometimes accompanied by chill. Examination would show tenderness in one or other loin over the kidney, usually mild and transient. This rise in temperature occurred just after the suprapubic wound had healed to a sufficient extent so that urination *per urethram* had taken place for the first time since operation. Post-operative notes on patients in the hospital were quoted to illustrate this point, which seemed to be explained by assuming that the bladder for a longer or shorter period quiescent, had become hypertonic, and on first resuming its function of the expulsion of urine had caused the reflux to appear, resulting in the upward transfer of infected material to the kidney. In the treatment of renal infections the strongest weapon we possessed was water, by the diuretic action of which the kidney was enabled to rid itself of the infecting organisms. Water should be regarded as a medicine and as definite orders given concerning its administration as would be given in case of morphine. He administered 3500 to 4000 c.c. of water in 24 hours. He felt that the action of salol and hexamethylenamine was at best but feeble. Vaccines he had found to be of no value. Removal of foci of infection elsewhere in the body was most important. The local treatment of renal infections by injection of solutions into the renal pelvis was a very important procedure concerning the value of which there could be no doubt. In conclusion, Dr. Quimby emphasized the importance of early recognition and treatment of infections of the kidney, and that, whether acute or chronic, blood-borne or ascending, these infections were always secondary to a primary focus elsewhere than in the kidney itself. Therefore, if a cure could be accomplished by other means than nephrectomy it would be most assured after this primary focus had been adequately controlled.

Dr. EDWIN BEER said it was a great pleasure to listen to Dr. Quimby's very suggestive paper, in which he had touched upon some important experimental work he had been doing and made use of it in explaining some of the difficulties we had had in the past in attempting to explain renal infections. It was surprising how much of what was known on this subject had come from work done in surgical laboratories. Pathologists had given us very little light on this

question whereas surgical clinics and surgical laboratories had given us almost all the experimental work we had in regard to the pathogenesis of pyelitis, pyelonephritis and tuberculosis of the kidneys. If one read the books of thirty years ago one could readily see how much progress had been made which had made it possible for Dr. Quimby to express himself as he had tonight. Limiting himself to a discussion of the pathology and treatment of kidney infections, Dr. Beer said that the staphylococcus, pneumococcus and colon bacillus were almost always carried to the kidneys through the blood stream. The question as to whether the colon group could be lymphogenic he felt was not definitely settled. It was well known that the veins and arteries were accompanied by lymphatics and that there were blood vessels passing from the kidney to the lower part of the ureter, so that the ureter was supplied with blood from the kidney. It might be possible for infection to ascend in these perivascular lymph vessels. He thought we could not deny the possibility of lymphatic infection especially where previous inflammation had existed in the lower tract. To what extent refluxes were responsible it was difficult to say, but he would like to ask Dr. Quimby why inflammation did not occur more frequently in cases in which a ureteral catheter was passed through an infected bladder. It seemed to him that the infrequency of these infections was a point against the ascending theory of infection by refluxes. So far as treatment was concerned cases should be separated diagnostically into two groups: First, the colon bacilli group, in which the cases could be treated with much milder methods than in cases infected with staphylococci or streptococci, etc.; the latter group almost always required kidney operations at times even nephrectomy. In colon bacillus infection free drainage and copious water administration was usually sufficient, though occasionally decapsulation was needed. Thus in the treatment one must be guided by the causative agent and nephrectomy was practically never indicated in the colon bacilli cases while in the coccus cases it might be life-saving.

Dr. Leo Buerger said he thought everyone had been stimulated by Dr. Quimby's interesting observations, in which the latter had followed a long a line of thought touched upon by a number of writers. Ascending infection was important, but that it was as important as Dr. Quimby would have us believe, was very doubtful. As for the experiments themselves, Dr. Buerger said he would like to have Dr. Quimby explain if the patency of the ureter in the centripetal sense was not an artifact produced by experiments. Everyone was familiar with the antagonistic action of the sphincter and the detrusor muscle. With artificial stimulation of the sphincters one can obtain an antagonistic relaxation of the detrusor muscle. During the period of such relaxation the ureter orifices might have lost sufficient tonus to permit of the regurgitation of urine. He also suggested that in following out these studies it would be of value to stimulate the pudic nerve, the *nervi erigens* and the internal sphincter, with the idea of exciting a sphincter spasm, and to observe whether the detrusor, under such conditions, was hypotonic, and whether it then would allow regurgitation to take place. Furthermore, Dr. Buerger called attention to certain of his own observations made as far back as ten years ago, that would support some of Dr. Quimby's contentions. When collargol was first employed in pyelography he had observed and reported the rapid invasion of the renal parenchyma and even the cortex with collargol precipitate. Such findings demonstrated beautifully the facility with which solutions were imbibed, as it were, by the renal organ, even when excessive intrapelvic pressure was absent. Given ureterorenal reflux, therefore, the possibility of infection by direct extension through the tubules was readily understood. The rôle of obstruction to urinary outflow from the kidney should not be underestimated. It was effective as a cause, both through congenital or acquired coarctations. So that it was safe to conclude that such factors were pre-disposing moments to renal infection whether by the ascending or descending route. As to the routine adoption of forcing fluids in renal infection, especially of the bacillus colon type, he might appear audacious to take issue with the almost universally accepted notion. Although not wishing to deprecate the value of fluids, certain observations made with the cystoscope had aroused the thought that excessive drinking of water might cause retention in the renal pelvis and thus add to the factors that tended to intensify the dangers of renal infection. Swelling and inflammatory processes near or at the ureteropelvic junction were frequently associated with repeated attacks of renal infection, and during acute exacerbations were productive of retention in the renal pelvis. So that when we cystoscoped cases during an acute attack with high fever, we could demonstrate that the kidneys did not rid themselves of the large amounts of fluid excreted so that an acute hydronephrosis become established. Such nephrosis might contain absolutely clear urine with but a rare pus cell in the specimen; and still evacuation of the retained urine through the catheter resulted in prompt relief. If we gave a large amount of water to these patients and cystoscoped during an attack, he would find that with the catheter in the ureter he would have a rapid intermittent excretion of water, but as soon as the renal pelvis was entered there was an enormous flow, quite out of proportion to the quantity excreted in a given time through the ureter. Mere emptying of the pelvis of the kidney would result in immediate improvement. So that he felt that even the imbibition of fluids might be overdone when it resulted in overdistension of the renal pelvis. The explanation that Dr. Quimby offered for urethral fever, he did not believe satisfactory. For how would he explain the occurrence of fever in prostatectomy patients in whom, with the wound still open, a catheter or sound was passed merely into the posterior *urethra* without entry into the bladder. Surely reflux and back pressure into the ureters should not occur with the suprapubic fistula still patent. There were two types of cases, one in which Dr. Quimby's explanation might obtain, and the other in which absorption through the raw urethra might be the deciding factor. In the first instance, the patient had a chill and fever occurring synchronously with the first attempt to void, and retention of urine was regularly found. Here the possibility of reflux could not be excluded, although usually some urine was passed through the urethra. In the second type, however, retention was *absent*, the patient passes an ounce or two of cloudy, often bloody, urine, and with this symptoms appeared.

Since this might occur without retention with the suprapubic fistula *still open*, it would appear that absorption through the raw posterior urethra was a more plausible explanation for the manifestations. As for treatment, Dr. Beer had given a very succinct outline, but he differed from him in the relative value of lavage. He believed in it if carefully carried out, particularly in the recurrent and chronic cases. A child was brought to him who had had a pyelitis for almost six years. She had never been without pus in the urine, and never more than one month without a chill and temperature. The child was anesthetized and the renal pelves washed out. Improvement occurred immediately, attacks no longer occurred, and the patient was on the road to recovery. Finally, Dr. Buerger called attention to a type of acute suppurative nephritis that was doubtless of hematogenous origin, in which there was a diffuse exudative inflammation with polynuclear intracanalicular and intratubular exudate. These cases might show but little pus in the catheterized specimens, and did not have any urinary retention in the renal pelvis. In the latter regard, they were distinctly different from the usual colon bacillus type of pyelitis or pyelonephritis. Delafield, he believed, had already alluded to this interesting form of infection.

Dr. Alfred T. Osgood said they had all believed that ascending infection took place; how or why it took place was a matter which had been unexplained. There were cases in which the ureter was dilated and abnormal and the bladder hypertonic so that it was easy for the fluid in the bladder to mingle with the fluid in the kidney. To find another way in which this infection took place was most interesting. They always looked for a revelation from Dr. Quimby and they had not been disappointed tonight. They were glad also to have light upon the cause of the catheter

or ureteral chill. It was also important for those who taught to have something to say in explanation of the "back pressure," an expression which they had been using in a rather loose way. In this respect Dr. Quimby's views had helped them very much. He agreed with what Dr. Quimby had said, especially as to the use of water as a means of combatting kidney infection; and what he had said in connection with the physiology of the ureter made it apparent that an abundance of water was indicated. He had hoped they might hear some other explanations, and particularly that some definite light would be thrown on the question of colon bacillus infections of the kidney and their treatment. Personally he was very apt to refer the patient with a colon bacillus infection of the kidneys back to the enterologist and ask that he keep these organisms within their natural bounds. That was the fundamental problem in dealing with colon bacillus infections.

Dr. E. L. KEYES said he need scarcely call Dr. Quimby's attention to the fact that his paper was suggestive. The onslaught he had already suffered had proven the value of his remarks fully as much as anything he could say by way of flattery to him, though he could not fail to add his tribute to what he considered a most illuminating and suggestive paper, which he should now proceed to disagree with as much as I know how. In the first place, Dr. Buerger had stirred him up with his pelvic lavage. He could not believe that a washing out of the kidney pelvis once with any known fluid would destroy bacteria that had been resident in at least the submucosa of that kidney pelvis for six years. He did believe the clinical facts related by Dr. Buerger. Similar clinical facts had been reported by many observers and we had all met them in our own practice; but they were attributable to the mere ureter catherization. The first one to suggest this theory was Dr. Howard Lilienthal who suggested that a badly draining pelvis might have its ureter ironed out by a single catheterization to such an extent that it would relieve the retention. He cannot understand how a single washing would have much more than a carminative effect. In the second place, as to hexamethylenamine, this agent was in some cases just as much the drug for the treatment of renal infections as intermittent catheterization was in the treatment of prostatic retention. They treated prostatic retention in hospitals by preference, either by immediately operating on the bladder to get permanent drainage or by tying in a catheter to get permanent drainage. He was quite satisfied that this treatment was elected because urologists were careless or lazy. If one found a competent trained nurse and had him pass the catheter with sufficient gentleness and regularity one got decompression of the bladder with far less reaction than by retained catheter or operation. Now similar care was called for in the use of hexamethylenamine. In illustration. Dr. Keyes cited a case of pyelitis. A woman twenty-two years ago had her first child and had an attack of pyelitis. He examined the urine himself and gave the hexamethylenamine himself. The temperature immediately fell—whether because of the hexamethylenamine or not—and day by day watching the urine the pus grew less, the bacteria disappeared, and finally the albumin disappeared, the treatment being kept up for about three months. The patient then remained well until this year, with urinalysis from time to time,—perhaps 150 between then and now (no cultures being taken) which showed no pus, no bacteria, and no albumin. This year she had a violent bronchitis and her pyelitis started up again as a complication. Watching the acidity of the urine and giving full doses of hexamethylenamine it was remarkable how one could bring down the amount of pus in the urine. But the action of the hexamethylenamine must be controlled by daily testing the acidity of the urine (and acidifying with acid phosphate, if necessary), and watching the preponderance of pus cells and epithelials (with the microscope, for urine looks just the same whether it is full of pus cells or not). Dr. Keyes questioned whether hexamethylenamine was of any value in the acute conditions associated with fever. There, Dr. Quimby's water treatment was good, and the lapse of time and the grace of God was even better. The urethral chill was the next point; no one knew what the urethral chill was. The urethral chill, as casually described by Sir Henry Thompson, was the reaction following the passage of the sound. Dr. Quimby might hitch that up with his reflux. He wished he would do it.

Dr. ABRAHAM HYMAN said he was interested in Dr. Quimby's ingenious explanation of the ascending route of infection but he hardly thought it would account for many of the cases. Some eight or nine years ago he had undertaken experiments with reference to the action of the sphincter of the bladder before and after prostratectomy. He took normal bladders, those associated with enlarged prostates, and those after prostatectomy had been performed. He made the observations by injecting argyrol and radiographing the bladders. In the normal bladders he did not find a single case in which there was reflux from the bladder up into the ureter. In normal bladders it was generally agreed that unless there was very considerable tension there was no reflux. One would think that in bladders associated with enlarged prostates a reflux would very often be encountered, but the surprising thing was that we did not see refluxes in any of these cases. It was different with a catheter in the ureteral orifice. With the catheter in the ureter one would frequently see a reflux. Tests were made with the ureteral catheter and methylene blue solution. By introducing the blue fluid in the bladder and a meteral catheter in the pelvis, the solution could at times be recovered through the catheter. A recent case brought out in a striking way how careful one must be with regard to the ureteral reflux. The patient was admitted to the hospital complaining of right-sided lumbar pain and the history of a previous kidney operation on the opposite side. The *x*-ray showed calculi in the right kidney and ureter. The right ureter was catheterized, and from this side cloudy urine was obtained. On the opposite side, the side that had been operated upon, the catheter was passed all the way up to the pelvis and two or three c c. of urine were obtained containing 1/10 per cent. of urea. The urine from the right side contained 1 per cent. urea, and showed a faint trace of indigo carmine. A diagnosis was made of bilateral renal disease. At operation it was found that there was no kidney on the left side. The only way these findings could be explained was that the urine from the left kidney was a reflux of the bladder urine. As regards pelvic lavage, Dr. Hyman said he was of the opinion that it was not pelvic lavage but drainage per ureteral catheter which was effective in these infections. He thought he had demonstrated that by introducing the ureteral catheter and allowing it to remain in situ for hours at a time, after a while marked improvement had been noted. Dr. Hyman referred to the work of Dr. Kidd of London who had had a very large experience with pyelitis and had noted good results from the use of alkalies. Dr. Kidd had given up the use of hexamethylenamine and claimed that he saved many patients by giving very large doses of alkalies.

Dr. BENJAMIN S. BARRINGER said he wished to speak of pelvic lavage. He agreed with what had been said in regard to the value of this procedure. He cited a case of infection of the kidney in a man who was a bad alcoholic. He had had a chill and was in bad condition. The usual remedies had failed. He washed out the pelvis of the kidney and the man improved. Someone suggested formalin solution. He did not recall the strength of the solution, but this was used on one or two occasions and the man recovered.

Dr. H. F. RATHBUN said he was surprised that no one had spoken before of the use of alkalies. In his experience alkalies were practically specific in colon bacilli infections of the kidneys, in some cases in small doses and in others in large doses, together with copious colonic irrigations. He was also a great believer in pelvic lavage, especially in subsiding cases. He thought Dr. Beer's case was one of stricture of the ureter. He had seen many cases of stricture of the ureter cured by one cystoscopy.

Dr. COLIN L. BEGG said the paper was a very delightful one and stimulated one to think. It had always seemed to him in the treatment of pyelitis, which he had considered to be associated with pyonephritis, that one should differentiate between acute cases and

chronic cases. He had obtained the best results in acute conditions by leaving them locally absolutely alone and treating them systemically. When there was a bowel condition that might be a factor in the infection he forced water and the alkalies in the acute stages, but when the condition assumed a chronic form, whether the case was due to stricture of the ureter or not, it seemed to him that a large number of cases had been absolutely cured by lavage. Also in chronic cases he gave not only hexamethylenamine, but thought he obtained better results by a mixture of hexamethylenamine and benzoate of soda.

Dr. QUIMBY, in closing the discussion, said he felt very much honored by the voluminous discussion. It seemed that none of them were very far from agreement on these matters; it was only in an occasional detail that they differed. As to the point brought up by Dr. Beer, who felt that there was still something to be said for the thesis that infection traveled by way of the lymphatics, it might be possible that infection was thus transmitted, but it was harder to visualize an infection travelling that way than by the reflux he had described. When one spoke of the lymphatics of the ureter he must mean the perivascular lymph spaces in which the course of the lymph, so far as we knew, followed the blood current. He knew of no channels that went the whole length of the ureter up or down, and when a portion of the ureter was resected it would live by its collateral circulation. Therefore he could not feel that the lymphatics took any great part in conveying infection to the kidney, and must take issue with Dr. Beer on this point. As to why one got no infection when he passed a ureteral catheter he did not know, but nevertheless clinical experience bore out that fact. They knew that one often passed a catheter through a bladder infected by bacteria, and when such a catheter was in place a reflux of bladder contents upward might occur. The reason infection of the kidney did not occur in such cases, he would suggest, was that the distending fluid introduced into the bladder was practically always antiseptic, and this might account for the demise of some of the bacteria. Furthermore, it was probable that in the majority of instances in which catheters were passed into the ureter, previous measures had been employed to promote diuresis. In the presence of a copious flow away from the kidney organisms which might have been introduced by the catheter or by reflux were again washed down. As a corollary to his discussion Dr. Beers had asked his opinion as to an apparent specificity of certain organisms to reproduce in second individuals in the same location as they occupied in the primary individual. He referred to the work that had been done and was being continued in Rochester. A patient had an infected kidney, the organisms from this kidney were cultured, the cultures injected into the teeth of dogs and the cavities in the teeth closed by dental measures; subsequently infection occurred in the kidney. That was very astounding. Dr. Beer had asked him to express an opinion as to specific electivity. As an individual he was withholding his judgment. It sounded entirely visionary. He was not yet convinced of the theory of specificity of organisms of which Dr. Rosenow was an exponent. Dr. Oswald had suggested that many renal infections, especially those of the colon type, were due to the intestinal tract. That was undoubtedly true. Everyone who observed patients carefully found that the kidney owed many of its infections to impairment of the intestinal function. It was not an infrequent occurrence to find an impaired kidney following amebic dysentery in the tropics, and milder infectious conditions secondary to ordinary chronic constipation might have a somewhat similar effect. Dr. Buerger had suggested as a possible explanation of the reflux that stimulation of the sphincter was followed by contraction and with this contraction there was a relaxation of the detrusor muscle, thus permitting reflux. Physiologists had shown that where a muscle complex existed, one muscle contracted when another relaxed, but in the case of the sphincter and the detussor each muscle was supplied by a different nerve. The whole problem of innervation was not sufficiently worked out. Their experiments seemed to show that the reflux had been easily produced by other means than stimulation of the sphincter by the catheter; for instance, the introduction of fluid through a fine hypodermic needle passed through the bladder wall. When this procedure was employed the reflux occurred just the same as when the catheter was introduced. He might not have made himself clear in claiming that a reflux might be responsible for the crisis of fever in a patient who had had a prostatectomy. Following prostatectomy the bladder had been out of commission for varying periods of time, roughly two weeks. There was during this period no impediment to the outlet from the bladder. Before the rise in temperature occurred it was easy for the urine to leave the bladder by the suprapubic opening. As this opening contracted and as resistance thus increased, the bladder became distended. Then for the first time since it had been opened it emptied its contents by increasing the intravesical pressure. As it contracted some of its contents entered the kidney by reflux, carrying infection and causing a chill. Regarding the mechanism of the chill subsequent to the use of either sound or catheter, it made no difference which was used. It was the passage of anything over the trigone or even distention of the bladder, in fact anything that stimulated a hypertonic bladder to contract caused reflux. He did not think the chill was due to the raw surface, because that had been present all the time. As to the treatment, he would like to know whether Dr. Keyes gave hexamethylenamine without forcing fluids.

Dr. KEYES replied that he did.

Dr. QUIMBY said he should then begin using this agent with more faith than he had been doing. As to the giving of water, of course this could be overdone, but he felt very strongly that it was rather rare to find a patient in whom the excessive ingestion of water had been harmful. He had yet to see a patient who had had too much water. Recently he had had a patient in the hospital suffering from diabetes insipidus who was taking 35 or 40 liters of water a day without detriment to his kidneys. The case Dr. Hyman had cited was very interesting. It made one feel that it was very necessary to have a pyelogram of these cases. Dr. Kidd of London had written an excellent book on renal infections, and one he would have liked better if it had not contained so much vituperation. Dr. Kidd indorsed the treatment of pyelitis with alkalies. This was not new, for alkalies had been used for a long time, especially for pyelitis in infancy. The pediatricians had found the greatest benefit to come from the use of alkalies in pyelitis in children. If after a period of treatment with alkalies the infection was not conquered, changing the reaction to the acid side might have the desired result. Though of the greatest benefit in childhood, this method of treatment had a somewhat analogous result in adults. The basis of this treatment was that every bacterium grew best at an optimum point of hydrogen ionization according to the individual strain of the bacterium. Too much acid or too much alkali might destroy it.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

MEDICAL EXAMINERS OF WYOMING.

Cheyenne, June 6-8, 1921.

(*Continued from page* 129.)

SURGERY.

1. Give the symptoms, diagnosis, and treatment of hemorrhage from the middle meningeal artery.

2. What is surgical shock? Discuss its signs, symptoms, prevention, and treatment.

3. Differentiate cholecystitis, appendicitis, and salpingitis.

4. Differentiate the coma from injury, cerebral hemorrhage, uremia, opium poisoning, and acute alcoholism.

5. Give the diagnosis and treatment of perforated gastric ulcer.

6. Describe the technique of an operation for indirect inguinal hernia.

7. Give the diagnosis and treatment of fracture of the internal condyle of the humerus.

8. Given a tumor of the female breast, how would you

diagnose probable malignancy, and what surgical treatment would you adopt?

9. Discuss the constitutional reaction and treatment of burns.

10. Differentiate dislocation of the head of the femur from fracture of the neck of the femur, and outline treatment for each.

11. Discuss the etiology, diagnosis, and treatment of gastric carcinoma.

ANSWERS.

SURGERY.

1. MIDDLE MENINGEAL HEMORRHAGE. *"Symptoms:* When not obscured by some other cerebral lesion, the typical symptoms are—(1) temporary concussion; (2) a lucid interval of a few minutes to a few hours; (3) gradually increasing drowsiness ending in coma. If the hemorrhage is rapid or there is cerebral laceration as well, there may be no interval of consciousness. In addition there may be, from pressure on the motor area, twitching of the corresponding parts followed by paralysis. The pupil on the injured side becomes first fixed and dilated, the other following. When the coma is well marked the pulse is slow and full, and the breathing is stertorous. When the brain is lacerated there are alternating tonic contraction and relaxation of the muscles supplied from the injured area. The *Diagnosis* is difficult, unless the symptoms are typical, and they seldom are. *Treatment* consists in trephining, removing the blood-clot, and stopping the bleeding. A flap is turned down, and a trephine hole made over a spot 1½ inches above and behind the external angular process exposes the anterior branch. After the blood-clot is removed the bleeding-point is searched for and tied; if it is not seen, more bone must be clipped away. If the bleeding comes from a canal in the bone, it may be stopped with gauze, sponge, or aseptic wax. If the brain then expands, the bone may be replaced and the wound stitched up without drainage; if not, the bone must not be replaced, and the wound should be drained for twenty-four hours. The posterior branch can be reached by a hole made just below the parietal eminence."—(*Aids to Surgery.*)

2. *Shock* is the name given to a sudden and general depression of the vital powers; due to some strong stimulation (such as injury or emotion), acting on the vital centers in the medulla and producing vasomotor paralysis. Shock is *primary* when the symptoms appear promptly; it is *secondary* when the symptoms don't appear for several hours (often observed after railway accidents, intoxication, etc.)

Symptoms of shock.—The blood pressure is lowered considerably; the pulse is very compressible, rapid, short, and often difficult to count; the respirations are quick, sighing, and irregular; the skin is cold, clammy, and pale; perspiration may be profuse, but other secretions are diminished; body temperature is subnormal; muscles are relaxed; and reflexes are diminished.

Treatment.—Place the patient in the recumbent position, with the head low, apply warmth to the body, administer a stimulant, and give a hot saline infusion; morphine, hypodermically, may be necessary for the relief of pain. Adrenalin solution is administered into the arterial system.

In surgical operations *shock may be largely prevented* by reassuring nervous patients, keeping the patient warm, the avoidance of the excessive catharsis, and semi-starvation that often prevails before operation, the administration of strychnine and atropine before operation, the avoidance of delay and undue handling of parts during the operation, prompt checking of hemorrhage, and by using the utmost gentleness. With a view to preventing the passage of exciting afferent impulses, Crile advocates "blocking" of the nerves by the injection of a 1 per cent. solution of eucaine into their substance on the proximal side of the field of operation.

3. In *cholecystitis* there are pain, tenderness, and muscular rigidity over the area of the gall-bladder, also fever, rapid pulse, vomiting and leucocytosis. In *appendicitis*, the rigidity and tenderness are lower down, and the fever and leucocytosis are not so pronounced at the beginning of the disease; the pain is of sudden onset and is localized in the right iliac fossa; there is abdominal rigidity, chiefly of the right rectus muscle; there are usually fever, nausea, vomiting, and constipation.

Salpingitis is diagnosed by: A dragging sensation in the neighborhood of the affected tube; colicky pain, which is increased on exertion or even on standing; abdominal tenderness; menstrual disorders, as amenorrhea, metrorrhagia, dysmenorrhea, menorrhagia; dyspareunia; there may be septic symptoms and peritonitis; sterility generally ensues. On examination there will be found a fullness in Douglas' pouch and one or both lateral fornices; in these latter will be felt either the tubes, distorted and possibly adherent, or a sausage-shaped tumor, which is very painful; the uterus is retroverted or retroflexed, and may be bound down by adhesions; there may be an intermittent expulsion of pus accompanied and preceded by a burning pelvic pain.

4. The following table (from Eisendrath's *Surgical Diagnosis*) gives the diagnosis:

COMA FROM INTRACRANIAL INJURY.	APOPLECTIC COMA.	UREMIC COMA.	ALCOHOLIC COMA.	OPIUM POISONING.
Deep coma; may have history of onset after fall or injury. Evidence of fracture of vertex or base.	Deep coma; sudden onset. If any injury, only a scalp wound.	Deep coma. Slow onset unless convulsions have preceded the coma.	Can be aroused by supraorbital pressure unless very profound.	Can be aroused unless very deep.
Pupil dilated on side of lesion. Choked disc.	Pupils unequal or dilated. Contracted in hemorrhage into the pons.	Albuminuric retinitis.	Pupils normal or somewhat dilated.	Pupils contracted to pinpoint size.
Pulse very slow.	Pulse full and slow, often arteriosclerotic high-tension pulse.	Pulse rapid.	Pulse more rapid than normal and full.	Pulse rapid, may be irregular.
Respiration slow and stertorous.	Respiration slow and irregular.	Respiration frequent and irregular.	Regular respiration.	Respiration very slow—may be 6 to 8 per minute.
Temperature higher—101.	Temperature higher on paralyzed side, but lower in rectum.		May be low or normal.	
Urine normal or contains trace of albumin.	Urine contains trace of albumin, but may be same as in uremia.	Urine shows albumin, casts, and low urea percentage.	Normal.	Normal.
Hemiplegia on opposite side to that of injury. If contusion of brain is also present, may have generalized convulsions.	Hemiplegia with convulsions on one side.			

5. *Acute perforation* of a gastric ulcer is announced by "sudden violent pain in the epigastrium, which often radiates to the back, up to the left shoulder, and down

into the right iliac fossa. There are great tenderness, marked rigidity of the abdominal muscles, and shock of varying severity. There may be absence of liver dulness and movable dulness in the flanks. In about half the cases the stomach contents are vomited, but rarely is there any blood. In 10 per cent. of the cases there is no previous history of indigestion. There may be a leucocytosis.

"The *treatment* is immediate abdominal section, any existing shock being combated while the preparations for operation are under way. The incision is made in the middle line above the umbilicus, the perforation closed by a double row of Lembert's sutures of silk without excising the ulcer, the abdominal cavity cleansed with salt solution, and a gauze drain passed down to the vicinity of the perforation. If there is a generalized peritonitis, a second incision should be made above the pubes and the pelvis drained. In cases in which suture is impossible, the opening may be closed by the omentum, a loop of intestine, or gauze packing. The possibility of a second perforation should never be forgotten. Some surgeons perform gastroenterostomy at the time the perforation is closed, a practice which must necessarily increase the mortality, which, at present, is between 40 and 50 per cent."—(Stewart's *Surgery.*)

6. For *inguinal hernia* many operations are practised, but Bassini's is the most useful. "An incision 2½ inches long is made over the inguinal canal, exposing the structures of the cord and the external oblique. The external oblique fibers are split from the apex of the external ring to expose the canal. The sac is found, opened, emptied of its contents, and isolated from the structures of the cord up to the internal ring. If the hernia is irreducible, the intestine is freed and returned to the abdomen, omentum being ligatured and removed. The neck of the sac is then transfixed and tied with silk, and the fundus removed. The stump returns to the abdomen, three or four stitches are then passed through the conjoined tendon and arched fibers of the internal oblique and transversalis muscles above, and the deep part of Poupart's ligament below. These are tied behind the cord. The external oblique is then sutured in front of the cord, leaving just sufficient opening for it to pass through without pressure. The skin is then closed by a continuous stitch. The patient should be kept in bed for three weeks, and should not exert himself for at least six weeks. If the wound has suppurated, or if the case is one in which the abdominal muscles are weak, it is advisable that a light truss should be worn afterward for six months."—(From *Aids to Surgery.*)

7. Fracture of the internal condyle of the humerus. "This may be intra- or extra-capsular. The *extra-articular* variety consists of a mere displacement of the tip of the condyle (or epicondyle), and in young people is probably a separation of the epiphysis, which remains distinct from the shaft till the age of eighteen or nineteen years. The small fragment is drawn a little downwards by the muscles attached to it, and the fracture is readily detected by the usual signs; it may be associated with injury of the ulnar nerve. The *intra-articular* form is the more common, and extends from the condyloid ridge to the trochlear surface, implicating the coronoid and olecranon fossæ. The fragment is displaced a little upwards and backwards, the ulna usually accompanying it, so that on extending the elbow the olecranon appears unduly prominent, the lower end of the humerus projects anteriorly, and the forearms is slightly adducted (cubitus varus). The ulnar nerve may also be injured in this case.

"*Treatment.*—Flexion of the forearm will sometimes suffice to restore the fragment to its normal position; but this must be demonstrated by radiography. The limb under such circumstances is placed in an angular splint, and massage and passive movements are started early. Failing reposition by flexion, operation must be undertaken, and the fragment secured in position by wire or screw."—(Rose and Carless' *Manual of Surgery.*)

8. The two breasts should be inspected, and any abnormal appearance should be noted. Then the physician, standing behind the patient, should palpate the breast, noting the location of the lump, its size, shape, and consistence; this should be done by making firm pressure with the flat of the hand. Then the condition of the skin should be observed, to see if there is any abnormal attachment to the breast or tumor; note if the nipple is retracted; observe also if the breast is freely movable on the chest wall. The condition of the lymphatic glands in the axilla and above the clavicle should be observed. The main object of the diagnosis is to differentiate between a benign and a malignant tumor. In well-marked cases this is not difficult. *Benign tumors* grow slowly and gradually; as a rule, they are freely movable, firm, round, and the nearer they are to the skin the softer they are; they are not encapsulated, and do not cause retraction of the nipple or enlargement of the neighboring lymphatic glands. *Malignant tumors* grow rapidly, are movable in the early stages, but later become adherent to the skin or pectoralis major muscle; they are hard and immovable; the nipple is retracted, and the axillary lymphatic glands are enlarged; pain is a symptom; cachexia may be noticed, and there may be metastatic growths. But there is a large group of *doubtful cases*, which can only be diagnosed by a microscopical examination of a piece of the tumor.

The patient should be advised, if the tumor is *malignant* (and it is not an inoperable case), that prompt, thorough operation is absolutely necessary. If the tumor is *benign*, the tumor alone should be excised. In *doubtful* cases it is well to imagine the growth malignant until it is proved to be otherwise. If the breast is removed and the tumor is proved benign, the woman has lost a breast; whereas, if it is not removed, and the tumor should prove to be malignant, she will lose her life. The best plan is (with the consent of the patient) to prepare for a radical operation, excise a piece of the tumor, have it examined microscopically, and if it proves to be benign, remove the tumor; if it is malignant, remove the whole breast and neighboring lymphatic glands.

9. Burns. *Constitutional reaction:* The chief is shock. This depends chiefly upon the extent of the burn (rather than the depth) and also upon its situation; there may be congestion of the internal organs.

Treatment: "The constitutional effects must be treated first. Put the patient in bed with warm blankets, without disturbing the clothing over the burnt parts. Administer brandy by the mouth or rectum, and morphine to deaden pain, and prevent further shock. Saline infusion into the loose subcutaneous tissues or into a vein may be tried if the pulse is very small. Ether and strychnine may also be used.

When the patient reacts to these, the local injuries may be treated. For burns and scalds of the first and second degree, ointments are the most soothing. Powders such as zinc oxide and bismuth are also cooling and keep the part in good condition. For burns which destroy any part of the true skin, ointments and antiseptics are dangerous, the one on account of sepsis which occurs beneath it, and the other from the danger of absorption of the poisonous drug. Picric acid in 5 per cent. solution may be painted over shallow burns, as it forms a skin, and is to some extent antiseptic. Boric acid, as powder or in moist lint, is one of the best dressings, provided it is changed very frequently. The part may be treated with peroxide of hydrogen daily in addition. When granulations have formed, the part is treated as an open wound with aseptic dressing. All dead pieces of skin should be snipped off at each dressing as they die, and as soon as possible skin grafts are applied. Subsequent contraction of scars is treated by plastic operation."—(Buchanan.)

10. In fracture of the neck of the femur, the head of the femur will be found in the acetabulum; in dislocation, the acetabulum will be empty, and the head of the femur will be found elsewhere, *e.g.* on the dorsum of the ilium. In the fracture, crepitus *may* be elicited; in the dislocation, never. In the dislocation, there is inversion and a fixed position of the limb, both of which are absent in fracture. In fracture there is shortening and outward rotation.

The *treatment* in *intracapsular fracture* is: "Rest in bed with the leg between sandbags. Weight extension. If any signs of congestion of the lungs appear, the patient must get up and walk on crutches. Never disimpact, and always examine such cases very gently for fear of disimpaction." In *extracapsular fracture:* "Always disimpact in young, healthy patients when

there is much displacement. Long Liston's splint from the axilla to below the ankle, maintained from rotating by transverse bar. Limb is pulled on by weight attached by strapping and bandages well above the knee. Hodgen's splint is often more effectual than Liston's in reducing the deformity. Maintain splint and extension for six weeks." In *backward dislocations:* "Flex the knee and thigh in position of adduction. Adduct the thigh and evert simultaneously. Bring the leg down straight. Lift up, bend out, roll out. Direct traction of the thigh forward in a line at right angles to the body." In *forward dislocations:* "Thigh is flexed in a position of adduction. Adduct the thigh and then invert it. Bring the thigh down straight. Lift up, bend in, roll in."—(*Synopsis of Surgery.*)

11. *Gastric carcinoma* is very frequent and may involve any portion of the stomach, but most often affects the pylorus (60 per cent.), often starting from an old ulcer. It is more frequent in the male, and is unusual before the fortieth year. It may be of any variety, but is usually scirrhous in nature. It always begins in the mucous membrane, infiltrates the remaining coats of the stomach, and finally invades the surrounding organs, particularly the liver and pancreas. Perforation of the stomach occasionally occurs. The lymphatic glands, particularly those along the lesser curvature, are invaded at an early period, and distant metastases also may occur. The disease is fatal in from a few months to two years or longer, according to the nature and situation of the growth.

"The *symptoms* at first are those of chronic gastritis or nervous dyspepsia, *i.e.* interference with the appetite, thirst, a sense of fulness, eructations, nausea, vomiting, and usually constipation. Pain in the epigastrium and back may be an early symptom, but is sometimes absent in even the later stages; it may be increased or relieved by food. If in spite of careful medical treatment, symptoms of this character persist for a month or longer, and are associated with a progressive loss of weight, in a patient past forty, one should always suspect carcinoma, and advise an exploratory incision, which is the most reliable diagnostic measure. This is the time for successful surgical treatment. Among the later symptoms are coffee-ground vomit, cachexia, palpable tumor, ascites, distention of the superficial abdominal veins, swelling of the legs, femoral phlebitis, and jaundice owing to involvement of the common bile duct. Metastases in Douglas' pouch or in the ovaries may occur. The laboratory methods of diagnosis are unreliable in the early stages, and are of the greatest value only when the growth is inoperable. At this time examination of the gastric contents shows an absence of free hydrochloric acid and an increase in the amount of lactic acid, both of which conditions may be found in other gastric diseases. Microscopic examination of the stomach contents may show small portions of the neoplasm and the Oppler-Boas bacilli, and these bacilli and occult blood may be found in the stools. The motor and absorptive powers of the stomach are lessened. Blood examination shows a reduction in the hemoglobin and an absence of the digestive leucocytosis. Finally may be mentioned the possibility of making a diagnosis by the esophagoscope, introduced into the stomach; by transillumination with an intragastric lamp, showing a tumor on the anterior wall; and by the *x*-rays, after the ingestion of an emulsion of bismuth, the tumor appearing as a marked indentation in the outline of the stomach. The situation of the growth has a marked influence on the symptoms. When the cardiac orifice is involved, the symptoms are those of stricture of the esophagus, and a tumor cannot be felt. When the growth is at the pylorus, the symptoms are those of dilatation of the stomach, and the tumor is more apt to be palpated. When neither orifice is involved, vomiting may be absent, and a tumor may or may not be felt, according to its size and situation.

"The *treatment* is exploratory incision, and if possible, removal of the growth by partial or complete gastrectomy. Kocher claims 8 per cent. of permanent cures from operation. If the cardiac orifice is involved, gastrostomy will be indicated for the purposes of feeding. In operable cancer of the pylorus gastroenterostomy may be performed, in order to allow the passage of food into the bowel. When the entire stomach is hopelessly invaded, the only possible measure which promises relief is jejunostomy, or the making of an artificial opening into the jejunum in order to feed the patient."—(Stewart's *Manual of Surgery.*)

Medical History.

CRITICAL AND DESULTORY REMARKS IN THE LIGHT OF THE HISTORY OF ANCIENT MEDICINE.*

By JONATHAN WRIGHT, M.D.,

PLEASANTVILLE, NEW YORK.

IV

It is not he who happens to announce a truth unsupported by the modern scientific tests for truth who has discovered a new fact, but he who confirms it by observation and experiment. This seems a fair statement of the arrogant way modern science has of claiming the inheritance of antiquity as its own. Another phrase may be found for the spirit which animates much of the method of science. Discovery is made by earnestly setting out with a definite end in view and resolutely pursuing it through the mazes of the laboratory and the clinic until, perhaps at the very back door of life through which he is about to slink away, the agnostic or the atheist, who thirsts after the immortality he denies, finds at last he has won it, with the fact he has dug up, the shining truth which illuminates his passage to the grave. I do not mean to say that this method has not been successful or that there is not a very efficient and useful force supplied by the acceptation of this stern code of science, but is this all there is to say about the method of the acquisition of knowledge? It is difficult to write of views such as these without letting just a little flicker of inward disrespect arrest outward attention if one holds the view that this is not the only way or the chief of the ways knowledge is acquired and lest the earnestness of the critic betray him into extravagances, it is best to acknowledge at once there are very many methods and very many different steps in most methods of acquiring it, but science should be alive to them all and not confine itself to a code whose chief claim to recognition is that it stimulates industry, for after all without that no method of science will be efficient.

Let us bar the subconscious for a moment—the unconscious if the psychologists will, though I deplore their word for it. As a man tosses across a hot or a bumpy pillow in the night, a flash of recognition shoots across his consciousness, alive to something that had not come to the surface before. As he loafs along a winding path the light strikes the tip of a tiny wave, a shadow passes over the foliage of distant trees. He carries something back with him to his laboratory he had not had before; whether it came out of the conscious or the unconscious, we need not stop to inquire, it comes out of both, probably, at the most unexpected and insignificant impulse of sense. I am not going to bring in Newton and his apple, for that incident has been a dismal failure, thus far, in the way of arresting the attention of men of science, as one may see by the concern exhibited as to whether it was a true story or not. Now it is of no consequence whether the laboratory is one of books or one of test tubes and microscopes, it may be the clinic if you will. Nor does it make any difference whether it is today or tomorrow or ten years later when he emerges in a zeitschrift with his treasure and shows it to all men. "Ah," brays the ass contentedly to the elephant, "it is knowledge only after you have made us know it." A hundred truths emerge thus every day, many of them buttressed by irrefragible proof as valid one day as a thousand days afterwards when they are recognized by the long eared, but ninety-nine of them perish for a thousand years, until some other restless sleeper or wide awake walker gets the flash again in a more propitious moment for the demonstration of that particular fact. However that is a little aside from the present interest though intimately connected with the main purpose of these papers.

Where did he get it? He knew he had it when he turned over in bed, he felt he knew when he stubbed his toe in the path. I am distressed to find I am up against the unconscious again, for I know so little about it, but I am aware that some man of science, perhaps most of them if they but knew and condescended to think of the problem in this light at all, would say: "Very likely, but the laboratory fed the unconscious or this is mere mysticism." I shall have to let it go at that, for there is so much of the time I am unconscious of the unconscious, that I must give way to those conscious of it all the time and allow no link to escape them in it between the laboratory and the zeitschrift. As for the rest, that is as God wills or as chance may have it and thus we escape mysticism. "Voila, justement ce qui fait que votre fille est muette." All the laboratory did was to offer evidence to his fellow men, who nine times out of ten don't see it—usually never do. Perhaps he has no evidence he knows will convince them, as is my trouble with the unconscious, and lets it go at that also, but he knows. His discovery was made elsewhere, it was only confirmed in the laboratory if, as is the exception, any one paid any attention to it at all. Any sort of proof goes as confirmation if it has to do with the fad in medicine fashionable for the moment. The trouble is that then it is confirmation usually of something which is not the truth. You will find the evidence of this in the thousands of tons of the zeitschrifts which repose in dust and neglect upon the innumerable shelves of libraries. Now there is something wrong with the method of science that makes a truth true in one decade and neglected in the next or even denied, and forgotten altogether in the next century. A learned man wept in public ten years ago (or is it quite ten?) with joy that we had discovered a cure for syphilis. Turn the pages of this number of this journal or of another at your elbow, and see how much of this rapture is left. You need not be very old to remember the early tuberculin days, not to speak of cancer cures put forth with less confidence in the rise of the later phases of the science of serology. Are we to ignore such things in a discussion of the results obtained with the methods of science promulgated with such a flourish now for several generations? Men of science are justified in their reluctance to admit such a human thing as medicine among the sciences since they demand a detachment man will not yield where his emotions for humanity are so easily excited, but we cannot here be drawn into a discussion of conchology to show that some of the objections to the methods of science observable in the study of man are to be found also in the study of shells.

*See Medical Record, November 26, 1921.

V

How are we to explain the way progress has exhibited itself in the evolution of medicine? Our researcher may read Aristotle or Paracelsus or Pasteur from title page to index and he absorbs a thousand truths, but none of them ever comes home to him as that flash of recognition, to which I have alluded, before he seeks his laboratory. They may stare man in the face for a thousand years and he takes no note of them. They are the inheritance of humanity, but until the environment calls them forth to fruition they lie dormant in the subconsciousness of civilized man, and they come forth in that moment of inspiration some god, the ancients would say, secretly instills into the hero's heart. It is not in books alone that that inheritance lies stored, we know, and I hope I shall be permitted space to refer to that also, but they contain a very large share of it, and just in so far as they are made to form an integral part with the present environment in the education and daily experience of medical men will the fruition be greater and the progress of medicine along lines of usefulness more marked. The atomic theory, despite the manifest absurdity of supposing that energy can work or the mind can conceive its workings without a conception of the minute divisibility of matter, lay dormant from the time of Democritus, in spite of Lucretius and its sporadic recognition throughout the ages, until a hundred years ago more or less; so we may say of the hypothesis of the ether. We have split the atom, it is true, but the inevitability and much of the suggestiveness of the atomic theory has always lain, yet for the most of the time unrecognized, at man's door ever since coherence of thought began. Fundamentally, as the only kind of matter, it is inconceivable, for the ancients as well as we had to invent an impossible ether to fill in between the granules of matter, yet so insistent has become the demand that we hear now and then of a granular ether, but what we are to do for filling between the granules of that I have not learned. With ultimate truths the mind of man is powerless to deal, but with pragmatic reality, if that is the term to use, in apposition to "das Ding an sich," he must deal and the atomic theory must be as much a reality to him as his walking stick or crutch. So with the other facts of which the history of science is the repository. The ether disappears in some of the interpretations of Einstein's theory, but it has thus far been indispensable.

Contagion, in its modern conception, is a corollary of the minute divisibility of matter. Without the latter how could we have gotten away from the solitary devils of disease? It lingered in the mind of primitive man and his conception, lacking sufficient breadth to make room for more than one cause of anything, his reasoning, was inevitable. "If I succeed in putting the devil of smallpox into my fellow men I will necessarily get rid of him myself and be cured." The imagination fails to grasp the magnitude of woes unnumbered that reigned in this world under such a conception of disease as that. We see how long before the truth was demonstrated in a laboratory, and if we went through all the pages of history we would see how frequently it appeared unrecognized. Practically it had for a thousand years put an end to this vice of the mind before it was fully understood and developed in its modern bearings. Let no one think that an assault on the dominating ideas as to the methods of science in the past generation or two renders the critic for the moment blind to the utility of laboratories in the broad sense of the term, where new ideas are subjected to the test of experience and new theories are worked out. But the laboratory and its routine as engines for the evolution and application of human energy is quite another thing from the origination of thought or its diffusion. In this respect, like all other tools with which man labors, they soon become dulled instruments. Pedantry and the rigidity of form creeps into processes and into language, modes of thought and forms of its expression. When a specialty in or out of the laboratory adopts a special lingo, outlandish and unfamiliar terms of technique in thought and its expression, it has opened the first door that leads to degeneration and decay and has closed behind it that avenue which best serves the convenience of the thought of the rest of mankind. A momentary halo may be thought to encircle the head of him who speaks a language his fellow men only dimly follow, but the days of the primitive medicine man and the tribal wizard are past. He who thus cuts himself off from the thought and sympathy of common people has lost much of his right to exist.

VI

Seneca even was not the first to say:[1] "Especially in swampy places there are minute animals that grow, which the eye cannot follow, and they all float through the air into the body through the mouth and nares and there they produce stubborn diseases." Varro, Cicero's learned friend, had also published[2] the fact a hundred years before, and perhaps they both had it from the Greek, but I will not hunt up the references there. I avail myself of the researches of Ilberg[3] for the Latin authors, but the more ancient evidence has met my eye also. Barring the still moot question of air contagion, does anyone want anything more concise and plain today than Seneca's words two thousand years ago? It would weary the reader, if not the writer, to seek out the number of times the assertion comes to light even in the literature which has survived. Now, was it Pasteur or Lister or Koch or some other modern man who first told his fellowmen the truth as to the bacterial etiology of disease? Is there then no engine of the origin of truth outside the boiler room of a laboratory? Or is it not only a half truth to say that there is some fault with the method of science in the diffusion of truth? It certainly is not the whole truth, because we know pretty well that it is necessary to change man's atmosphere, almost his nature, before anything so radical in the way of such a change in his thought can be brought about. He is blind in his lateral field of vision. His vision is blurred for the nearest objects. They lie in his path unseen for ages and on his blindness hangs the fate of empires and the miseries of humanity. Is it the laboratory that can make him see or the hand which thrusts before his eyes the pages of history? Neither probably very clearly, but one without the other is, in the long run, hopeless, and the stack rooms of libraries will continue to bulge in vain with forgotten zeitschrifts. With both possibly we can do better. It is worth trying, at any rate, in our

age and generation to add the laboratory of history to the laboratory of science.

How did this idea concerning bacterial etiology in the middle of the nineteenth century or a little later happen to spread over the whole earth this idea of Isocrates or of some older nature philosopher from whom he had it? Because the evidence was produced in the laboratory? Not at all; the clinical evidence, the circumstantial evidence, the most reliable evidence of all, the converging of a hundred indications all pointing to one thing, had existed always, had been always lying at man's door, and yet our historical era opens and runs for hundreds of years without man in the mass being fully aware of contagion at all. So if we attempt to impeach the laboratory man for his shortcomings we must apply the same censure to the historian of science, we must exhibit impartiality between camps so hostile as science and history as literature, but after all we cannot help feeling the real trouble is with the mental makeup of the "damned human race," as Mark Twain insisted.

A sort of dumb, instinctive blind feeling existed that caused man in the later centuries to flee from the face of the sick man. During the great plagues at Rome, Galen, the physician, and Marcus Aurelius, wisest of men, greatest of rulers, indoctrinated with the purest stoical philosophy of the Greeks, fortified with the iron valor of the Roman, fled from the devastation of armies by plagues and from the stricken cities, but nothing like any coherent idea of contagion arose. Boccaccio placed his ladies and cavaliers in gardens of delight and had them while away with erotic tales what short time they might steal from death by the plague in Florence; like sheep they resigned themselves to the providence of God.

As to sheep, Virgil had the fact of contagion, perhaps from Varro or Volumnella, when he wrote:

"Nec mala vicini pecoris contagia laedent."[4] Yet not until the last quarter of the nineteenth century after this was the stupid mind of man at last opened to the fact in all its bearings, and how? Not by using the highest, the rationalistic faculties of his mind, but he was swept away toward it on the wave of a frequently unreasoning enthusiasm for the particular and frequently misleading evidence furnished by the laboratory. There had lain the declaration of Seneca and his forerunners, there had existed a century or so back the statute, and for a short time the practice in Naples of regarding phthisis as contagious, the pages of history were full of accounts of the appalling evidence furnished by countless plagues, all in vain. We pass on for some future age to explain this marvel, with the remark that the time must be ripe, the environment right, for the germination of a truth, and that is all I am doing here, but I refuse to regard the laboratory as its sole revelation, although I am not sure but that we are cajoling ourselves with a paraphrase and a parable when we talk like that—about the "germination of truth," I mean. It has significance probably only in an age absorbed and warped with a contemplation of evolutionary theories. When mysticism is to the fore again, we may be sure another explanation, doubtless another paraphrase will be sought. At any rate let us leave our minds open to the claims of Seneca, Nero's friend, and Antrechau in 1721, as well as to those of the Japanese Kitasato in 1894, as being the discoverer of the plague. As for me, I am impressed with the idea that the man who first conceived the bacterial etiology of disease probably was a light sleeper at night or wandered in the woods in the day. The sons of men did not hearken to him, thus crying in the wilderness, but that is another story, a problem interesting and useful in itself whose existence is only to be elicited by a study of the pages of history, but whose solution baffles and confounds us.

VII

Incidentally I have driven my argument through the preceding lines with references to well-known historical facts which demonstrate how for thousands of years the truth stares man in the face and is not recognized, how it lies dormant in the traditions of a civilization, in the subconsciousness of generations, forced on him unawares, and because I believe it is easier to approach the sympathies of the human mind in incidental fashion so as not to arouse its combative tendencies, I take for the moment a roundabout way to illustrate how forms in which truth is framed for one age are utilized for truths, quite different, perhaps antagonistic, in another age. An illusion has just been made to the influence of the environment on the diffusion of what for a decade or two we are pleased to call truth, and elsewhere it has been urged that no one in the effort to accomplish it in current literature has the right to shock the sensibilities and tire the attention of one's readers by carelessness in the form of one's discourse. Cicero put the matter thus: "It may be true that one may have the right idea and that one cannot properly express it, but for any one to put his cogitations in written form, when he cannot so arrange and illustrate them as to attract the reader by feelings of pleasure is to impose rudely on the leisure of man and the rights of literature."[5] One may justly claim, and so far as I am concerned he has a claim on my sympathy, that we are not all born poets, or what is more rare, few of us are good prose writers, yet we feel we, too, have a message for the world, but to make no attempt, to flout the demand as silly and unreasonable, is the mark of a boor and a fool. It is for us to do our best, sink beneath the wave of literary mediocrity if we must, and we probably will, but swimming the best we can. To pretend there is no water at all or it is not deep enough for the leviathan of science, or it is all dry land and one is privileged to go as one pleases, is not the kind of excuse to which the world turns a sympathetic ear.

The scientific journals are trimming their edges to lighten the labor of their readers. It is not the wielding of the paper knife that causes fatigue or calls for assistance, it is the heaviness of the page. When paper was cheap and labor ill paid, any scribbler in science may have felt privileged to deface it and exploit the pressman's toil. It has to be paid for now out of slender salaries and wails innumerable are going up through all the broad domain of science in every land. Is it possible that out of this welter, in which as a best seller Charlie Chaplin rides triumphant on the wave and the Herr Professor sinks heavily beneath it, some good may come? Is it possible that men of science will be so chastened by the cost of print as to think it worth while to write well? The radical has in the past

sought support in the ranks of science for the uncouthness and rudeness of his propaganda, and after all turns on them in the gutter press and calls them high brow. But whether a man is a high brow or has an octagon front, if he expects to diffuse the propaganda of science or that of radicalism he must be mindful of the warning the master of form gave to the Roman world of his day. It was necessary to heed it then, it is now and it always will be, despite the danger of pushing it to preciosity and the pedantry of mere rhetoric. Propagandists in the name of altruism will not find as efficient a weapon in eccentricities of phrase and palling antithesis as in obeying the rules laid down by the ancients, when form was as necessary and as assiduously cultivated in their writings as philosophy.

VIII

This stability of form in art, or that part of art which is stable, is grounded in the emotions of the human soul. Certain cadences like those of Horace, "Pallida Mors aequo pulsat pede pauperum tabernas regumque turres,"[7] or of Virgil, when in the thunder of his line you hear the onrush of cavalry, drive the thought as well as the emotion into the consciousness of the reader. His heart swells and he sees the fact with a vividness quite foreign to the convictions one absorbs from medical science. It is no less illustrated when you take that one step from the sublime to the ridiculous. In another connection I have just employed his name and fame before, but you will find the tricks of form of Charlie Chaplin in the comic figurines dug up in the soil of ancient Greece and Rome. The art of the comedies of Aristophanes, of Molière, the first nighter who is on the outlook for something new and original applauds in the farces that fill the stage of modern Rome, Paris, New York. You will find neither tragedy nor comedy in the scientific essay, no appeal to form or art on the part of those who never tire in their efforts to drive into the people or their colleagues the truths they cling to while they last, nothing but exaggeration on the public platform, which revolts those who know, and flaming posters hiding the landscape from those who are tired.

There are two incidents which lately have come under my notice illustrating much of the substance of the matter with which we have been busy. Much entertained with the conversation of a waiter in a roadside restaurant on a country road in his reply to the apologies of a rather disheveled guest for his personal appearance, I was struck with the apothegm which fell from his lips:

"Many a noble heart beats beneath a dirty shirt." Not long after in the Tusculan Disputations I found Cicero quoting[6] from some ancient Greek:

"Wisdom often dwells beneath a dirty shirt." (Saepe est etiam sub palliolo sordido sapientia.)

A doctor, moved by experience of long standing with neuropsychiatric cases, wished inscribed over the door of an insane asylum an apothegm he ascribed to Galen. "*Employment* is Nature's best physician." Now, Galen did not say that. Galen said, and it was expressed still better by Celsus: "Exercise is Nature's best physician"—or something to that effect. Hippocrates said: "Nature is man's best physician." Cicero said philosophy is man's best physician in mental disorders, but also in teaching him to bear physical misfortunes and the sorrows and trials of life, but none of them ever said employment, or useful occupation, is a cure for anything. That came in with the rise of modern democracy, vaunting the nobility of labor. We have draped our word "employment" with a meaning not inherent at all in "exercise" or "philosophy." That is commonplace, and Galen was commonplace and so was Cicero, except for the marvels of his speech and his prose, and Celsus did not rise much above them in the quality of his mental fiber. Hippocrates' saying, however, has preserved a jewel of medical lore that is immortal, of the utmost significance and value and as near to absolute truth as we ever get in this life. It is true now and has been true for all ages, but that philosophy or that exercise is Nature's best physician are only half truths, sayings to be surrounded by limitations and pricked with numerous exceptions. Something of the same cast of phrase has englobed them as well as the apothegm of Hippocrates.

The apothegm of my friend of the restaurant had been altered long before he got hold of it, but I judged he was tinctured by tradition rather than by the culture of ancient learning, for I heard him relating also with much satisfaction how he had found water in the ground with a peach tree crotch. The Lord knows where he got his classical allusion. It had been altered, perhaps hundreds of years ago, because "sapientia" no longer dwells in the heart in our conceptions of physiology, no longer beneath a shirt, dirty or otherwise, though the poets still figure noble sentiments as dwelling in the heart. For the early Greek thought also dwelt there, but now it dwells beneath the dome of the calvarium. The syntax, however, was too good to be wasted, the elevation of the pressing thought of democracy has borrowed a phrase for a meaning foreign, if not to foreign thought, at least to Cicero when he used the form. In its old use it found all its weight in the example of Socrates, Diogenes, Caecilianus, with whom dirt and philosophy were not mutually antipathetic. In our day under the same phrase, the dignity of labor, the modern catchword (labor may be dignified for all I know), works its way to the front with the twist given to something supposed to be from Galen which certainly was entirely foreign to ancient thought. The nobleman under the dirty shirt, "a man for a' that and a' that," has put in his claim in ancient form. How the spirit of the present dominates antiquity and defaces the chronicles of history is apparent even in the pages preserved to us, and how much the foundations of ancient life are revealed in the analysis of modern interpretation is quite as apparent.[8]

The Second International Congress of the History of Medicine.—This Congress met at Paris, July 1-6, 1921, and a summary of its transactions appears in *Le Progrès Médical* for July 16, 1921, xlix, 29. The president was Singer of Oxford and delegates were present from France, Belgium, Great Britain, Italy, Czecho-Slovakia, Poland, Holland, Switzerland, Spain, Portugal, and other countries. Plantier read a paper on an epidemic of demonopathy in the Middle Ages, Giordane one on the history of catheterism, and Tricot-Royer one on the hospital history of Antwerp from the year 1000. Chauffard, Sr., recapitulated the arguments in connection with a faculty thesis of 1812; Belolhavek read a paper on the graduate theses of the University of Prague in the XVII century; Singer presented a MS. which may have been written by Guy de Chauliac; Raymond showed medieval pictures of syphilis and leprosy; Villaret and Moutier gave a historical account of intravenous medication; Basmadjian spoke of the medical history of Armenia, Van Andel of the medical men of Molière's comedies, Siegrist of medical astrology of the XV century, Jorge of typhus, epidemic encephalitis, and grip in the XVI century, Menetrier of medical anecdotes and incidents of the same period, taken from the tales of Eutrapel; Wickersheimer read a paper on the miraculous cures attributed to Cardinal Pierre of Luxembourg, Schrutz on Bohemian medicine of the XVI century, Guiart on the obstetrics of Ancient Egypt, Neveu on the "Holy City," Epidauros; Bugiel gave the history of Polish medicine; Herve gave an account of a man who once took *per os* virus from a rabid dog; Jeanselme spoke of the dietetic regimen of convents. The preceding are taken at random from a long list of papers presented during the Congress. The third session will take place next year in London.

The Patron Saints of Medicine.—It is not surprising that few medical men can give the names of the patron saints of their craft. The great Index-Catalogue of the Surgeon-General's Library at Washington, now in its third series, has not a single title bearing on these characters among its subjects, which means that no medical man has ever devoted a book, pamphlet, or journal article specifically to them, or at least that no such work is in the Surgeon-General's library. Garrison's superb "History of Medicine" does not mention them. In the large German work, "Biography of Prominent Physicians of All Countries and Ages" we find but three or four lines. "Damianus and Cosmas, two brother physicians, martyred in the persecution of Diocletian. Patron saints of surgeons." In the little work of Harnack on Christian Physicians, we find a paragraph on the brothers. They were the patrons of physicians and apothecaries. Their day is September 27. Tradition states that they came originally from Arabia but studied medicine in Syria and practised, among other places, at Aegea in Cilicia. In the great persecution of the Christians in 303 A.D., they were tortured and finally beheaded. Miracles are said to have been performed at their graves. Alleged relics of their existence are in Münich.

By far the best account of them in medical literature is found in Richer's "L'Art et la Médecine." It occurs on pages 396 and 397, with two illustrations numbered 257 and 258. It is stated that the brothers have been memorialized many times in religious art. Often they are represented as caring for patients, or in the act of amputating a leg. One of the most remarkable of these paintings is in the Louvre. It is a fragment by Francesco Pesello, otherwise known as Pesellino, who lived from 1426 to 1457. In the Museum of Offices, Florence, are portraits of the two saints by Bicci di Lorenzo (1350?-1427). Each holds in his right hand a small dressing forceps and in the left a box of ointment, indices of their profession. At the foot of the painting proper are two vignettes, one of which shows the two saints removing from a patient a leg which has turned black. Richer reproduces this painting in his figure 257. In the second painting, which is reproduced in figure 258 and which is now in the Ancient and Modern Gallery, Florence, the artist is Beato Angelico, who lived during the period 1387-1455. The two saints are supporting a black leg, evidently the seat of dry gangrene, which they are making ready to remove. The patient, confident of the power of the saints, has crossed his hands on his breast in resignation.

Much further information could doubtless be found about these worthies in religious literature and various works on saints and martyrs. Churches have been named for them, and there is one in the city of Rome in which the memorial day of the saints is duly honored. They are also the patrons of the pharmacists.

History of the University of Paris.—This institution dates from a period so remote that its beginnings are lost in obscurity. It originated in the neighborhood of the cathedral and was under the charge of the bishop and a special chancellor. The professors gave instruction in their own homes and only when these quarters proved insufficient did special buildings become necessary. In the XII century the celebrated Abelard, when he became a professor of the University, did much to advertise it and students flocked to him from all quarters. The residential district of the students became the Latin quarter. Four colleges composed the University in the early days, known respectively as the College of France, the College of Normandy, the College of Picardy, and the English College. The actual consolidation took place about the middle of the XIII century, and the college thus became the model for all similar institutions. The Renaissance, instead of causing a boom in university activities, had the opposite effect, and the institution began to lose prestige, becoming distinctly a back number. Other schools sprang into existence —the Polytechnic, Superior Normal, School of Oriental Languages, etc. Napoleon did something to rehabilitate the original University. The *École de Santé* became the medical college, and he created faculties for law, sciences, and letters, but they evidently were not successful as great metropolitan teaching bodies. It was not until the Third Empire that the period of university reform set in. The four faculties were grouped anew into a formation which also included the Superior Normal School, but left out the College of France. This arrangement persists at the present day.—*Gazette des Hôpitaux.*

CHRONIC ARTHRITIS.

BY LEONARD W. ELY, M.D.,

SAN FRANCISCO, CAL.

THE whole subject of chronic arthritis is a most confused one at the present time, and to the superficial observer the confusion seems well-nigh hopeless. To one, however, whose medical memory goes back for a quarter century the advancement of knowledge is evident, and the future is bright. Twenty-five years ago these cases were almost all grouped under the title of "chronic rheumatism," with one or two forms, such as tuberculosis, beginning to emerge from the obscurity. Since then a number of other forms have been identified and described as the result of patient investigation, but at every stage of the undertaking progress has been impeded by the publication of a mass of immature theory and high sounding speculation.

The first difficulty which confronts the student is in the matter of classification. The confusion here is so great and the difference of nomenclature so marked that in reading an article one has difficulty in identifying the disease the author is trying to describe. Thus "arthritis deformans" means different things to different people. Nichols and Richardson, who have done remarkable work in the pathology, under the name of "proliferative arthritis" describe a disease which Goldthwait, approaching the subject on its clinical side, calls "atrophic." Nichols and Richardson's "degenerative arthritis" is Goldthwait's "hypertrophic," and both correspond to the German "arthritis deformans." The English, on the other hand, call the former disease rheumatoid arthritis, and the latter osteoarthritis. Latterly some observers, especially Roentgenologists, have adopted the term "destructive" arthritis for any arthritis that shows rarefaction of the bone and irregularity of the cartilage, a particularly unfortunate term for it can be applied to every known form of the disease. Perhaps the most meaningless and unfortunate name of all however is "metabolic" arthritis. Health is metabolic equilibrium, disease is disturbed metabolism. To say, therefore, that an arthritis is due to disturbed metabolism is to say that it is due to disease.

The most prevalent method of classifying the arthritides is partly etiological, partly pathological, and partly clinical. Cases of which the cause is known are described, and then the cases of unknown cause are classified and named on a basis of some characteristic which the observer deems most important. This is the cause of all the confusion, and is untrustworthy and unscientific. It is possible to classify on a definite anatomical basis; and, until we are able to classify on an etiological basis, this is undoubtedly the best way.

All cases of chronic arthritis can be divided into two great classes or types, differing from each other not only in their pathology and clinical behavior, but also fundamentally in their appearance as revealed in the Roentgen picture. They differ also sharply in their etiology. In order to avoid making the present confusion worse, and in order to avoid the introduction of a new name into an already overburdened terminology, it is well simply to number them, and to label them Type I and Type II.

The first type includes the frank infections—tuberculosis, syphilis, typhoid, pneumococcus, coccidioidal granuloma, and diplostreptococcic arthritis from infection in the tonsil, in the deep urethra, and possibly in other organs as well. It includes Still's disease, and that form of multiarticular inflammation described by various writers as proliferative arthritis, atrophic arthritis, rheumatoid arthritis, etc. The fundamental pathological lesion of this type is a proliferative inflammation in the synovial membrane, in the bone marrow, or in both. It results in complete recovery, or in a fibrous or bony ankylosis. The Roentgen rays show rarefaction of the bone, thinning of the cartilage, and no new production of bone.*

The second type forms a well-defined clinical, etiological, and pathological entity, sharply differentiated from the preceding type. By the Germans it is known as arthritis deformans, by Nichols and Richardson as degenerative arthritis, by Goldthwait as hypertrophic arthritis, by the English as osteoarthritis, and by others as metabolic arthritis, senile arthritis, etc., etc. It is the chronic rheumatism of the elderly, and, when occurring in the terminal interphalangeal joints is known as Heberden's nodes, and is often erroneously considered a manifestation of gout.

The cause of this type of arthritis is unknown. Its primary pathological lesion is a necrosis in the bone and marrow in the immediate vicinity of the joint, but as yet there is no reliable evidence of the recovery of any organisms either from these areas of necrosis or from the joint fluid. As the *result* of this necrosis in the marrow, new bone is laid down at the joint surface, and especially at the lines of attachment of the capsule. This gives rise to the well-known spurring and lipping, so prominent in the *x*-ray picture and in the pathological specimen, and is responsible for most of the names be-

*Even in syphilitic arthritis new bone is not laid down in the immediate vicinity of the joint.

stowed upon the disease. The joint becomes mechanically damaged by the deformed and distorted bone ends, but the disease practically never results in either bony or fibrous ankylosis, except in spinal involvement. The new bone formation is permanent. Hence a joint once the seat of this disease never returns to normal, even if symptoms disappear.

Type I.

Pathology.—The members of this group differ in the details of their pathology, as they do in the details of their clinical manifestations and of their Roentgen picture, but in their essentials they are the same. One member of the group is found most often in the synovial membrane, another in the marrow, and a third almost always affects both, if it affects either. Tuberculosis may be taken as an exemplar of the group. In it the pathology seems to work out most beautifully to its logical termination.

The prime pathological feature of this type is a proliferative inflammation in the marrow or in the synovial membrane, or in both. The inflammation may start in either and may remain in it indefinitely, or at any time it may spread from one to the other. As the result of the inflammation in the marrow, the bone becomes thinner—rarefied. When the inflammation is more severe the bone dies, either in small pieces—bone-sand—or in larger pieces—sequestra. The buttress of bone beneath the articular cartilage is partially or completely absorbed, and the new granulation tissue, depriving the cartilage of its nutrition,* either perforates it, or spreads out in a layer under it and kills it in a greater or lesser extent. The infectious process is now in the joint, the synovial membrane is infected, and the other bone or bones of the articulation may be attacked by the inflammation spreading in under the margin of the cartilage.

When the disease starts in the synovial membrane, it may remain confined to that tissue, or it may spread into either or both bones, under the margin of the articular cartilage, and thus become a myelitis, as well as an arthritis. The synovial membrane may be soft, villous, and succulent, or it may be dry and fibrous. In the former case the joint will probably contain fluid of a greater or smaller amount; in the latter, the joint cavity may be obliterated by the fibrous adhesions between the bones, and between each bone and the synovial membrane. Hence arises the fibrous ankylosis, which later may be converted into bony, but is not often converted unless a pus infection be added.

Symptomatology.—Pain, local sensitiveness, and limitation of motion are common to all the members of this group. Increase of local temperature, muscular spasm, and muscular atrophy are usually present, especially in the severer forms, and with much bone involvement. With some, *e.g.* tuberculosis, deformity may be extreme, with others, *e.g.* syphilis, it is not prominent. As a rule the joint is swollen, and this swelling is always in the soft parts. *There is never any new production of bone outside the normal level*, in the immediate vicinity of the joints in this type of arthritis, in marked contrast to the second type. In the slow dry cases the joint may be shrunken, and its cavity may be replaced by a mass of dense adhesions; in other cases it may contain fluid, serous, flocculent, turbid, hemorrhagic, or purulent, as the case may be. I think it is a mistake to regard any kind of fluid as pathognomonic of any special disease.

Each member of the group has its peculiarities, which enable us to recognize it in the majority of instances, but in none of them is the recognition positive without the aid of the microscope. Thus, tuberculosis is almost always uniarticular, and usually has a slow, more or less progressive, steady course, while arthritis from tonsillar infection is often multiple, may be intermittent or remittent, and often involves the proximal interphalangeal and the metacarpophalangeal joints in the hands. Arthritis from a focus in the deep urethra may simulate the latter closely, though it rarely attacks the finger joints. It may, however, involve the metatarsophalangeal joints, and then is sometimes accompanied by a superficial osteomyelitis of the calcaneus—the so-called gonorrheal periostitis or exostosis. Syphilitic arthritis has no especial peculiarity which I ever have been able to discover. The theory that a syphilitic arthritis is always painless is not correct. It may be painless, especially if the synovial membrane alone is involved, but it may be just as painful as some cases of tuberculosis.

The Roentgen rays show a rarefaction of the bone in the immediate vicinity of the joint, with an irregularity of the joint line, and, owing to the disappearance or thinning of the cartilage, an approximation of the bone tissue of the two bones entering into the articulation. By the distribution, extent, and location of the rarefaction the skilled radiographer will usually be able to distinguish the member of the group to which the case belongs, but here again the identification is never positive, and the experienced operator rarely pretends that it is.

Diagnosis.—From what has been said it follows that an exact diagnosis cannot be made without the aid of the microscope, that is between the various members of the type. From the second great type, this type can be distinguished by the absence of new bone at the joint line. All the joints of this type look alike. A swollen joint is simply a swollen joint. Leaving aside the various laboratory tests, the diagnosis is made usually upon the history, the course of the disease, and the examination of the rest of the patient's body. Besides these we have one very important means—too often neglected—the therapeutic test with antisyphilitic treatment.

Treatment.—The prime indication for treatment of this form of arthritis is to remove the cause when it can be found. Tonsils that give rise to suspicion should be removed. Those which most often give trouble are the tough, buried, fibrous tonsils in patients who perhaps have not had a tonsilitis for many years. Lesions in the deep urethra should be cleaned up. Often a vesiculotomy will be necessary. Antisyphilitic treatment will work wonders in appropriate cases.

Tuberculosis cannot be treated on this principle. We have no means of eradicating the primary tuberculous focus, and we are forced to adopt other

*The cartilage is supposed to derive its nutrition in some unknown way from the marrow beneath it.

measures that cannot be described here. Suffice it to say that the main indication is to deprive the joint of function, either temporarily in the child or permanently in the adult.

There is a multiple progressive form of arthritis whose cause is unknown, which will defy all our attempts at treatment. In spite of everything we do, the joints become involved one after the other, deformed in flexion, until the patient becomes hopelessly bedridden, and dies after a longer or shorter time from some intercurrent disease, such as pneumonia or nephritis.

Type II.

Etiology.—This has always been the mysterious form of arthritis, not only in its etiology, but also in its pathology. Like every form of bone and joint disease this also has been ascribed to trauma, and, although the changes in and about the joint cannot possibly be explained on this hypothesis, most authorities still ascribe to trauma the leading rôle in the etiology. The disease does not result in laboratory animals when the bone and cartilage of their joints are injured.* Not only this, but the extensive changes in the interior of the bone cannot owe their origin to trauma, for the bone and marrow in this situation are well protected from every form of trauma except fracture. What these changes are we shall see presently. They have perhaps never been appreciated, but a knowledge of them is necessary if one would understand the disease.

In spite of the claims of several investigators, all the evidence at our disposal points to the conclusion that the disease is not of bacterial origin. With the facilities of a university laboratory at my disposal I have never been able to get a positive result from cultures taken from the bone marrow and from the joint fluid. Not only this, but the bone and joint changes in this form of arthritis are entirely different from those occurring in disease whose bacterial cause is known. We may, of course, take refuge in such vague terms as toxins and disturbed metabolism, but this is equivalent to admitting our ignorance. Disturbed metabolism is the definition of disease; metabolic equilibrium is health.

Although all the evidence is against the bacterial nature of the disease, yet the whole appearance of my specimens indicates that an infection of some sort is at the bottom of it. The most promising line of investigation, and one which my associates, Doctors Reed and Wyckoff, are pursuing with me is that the offending organism is a protozoon of some sort, most probably the *Amœba histolytica*, which is domiciled in the gastrointestinal tract and gains access almost invariably to the circulation through diseased alveolar processes of the jaws at the roots of decayed teeth. In two previous papers† I have called attention to the causal relationship of alveolar infection to this form of arthritis, and have heretofore ascribed to the alveolar osteomyelitis a direct causative rôle, but I have been obliged to abandon this theory, partly because one or two patients with the disease had perfectly sound teeth. Alveolar infection is probably one link in the etiology—a contributing cause.

Pathology.—To comprehend the pathological changes in this type of arthritis it is necessary in the first place to remember that all changes in the bone are the result of previous changes in the marrow. To speak of an inflammation of bone is a misnomer. The inflammation is in the marrow. The bone changes are secondary to this. Again, there is no such thing as an inflammation of cartilage. The cartilage simply reflects and suffers from inflammation in the subjacent bone marrow, and, to a lesser extent, from inflammation in the synovial membrane, that is, at and near its periphery. Chondritis, ostitis, and osteochondritis are impossibilities.

I have a number of excellent specimens of this type of arthritis in my possession, and I think that a study of them justifies the statement that the primary pathological change is a necrosis in the marrow in the immediate vicinity of the joint. What the cause of this necrosis is we do not know. We infer that it is an infection, though all our attempts to recover organisms have been fruitless. Depending, perhaps, upon the age of the process, these areas appear as sequestra, or as cysts. In what we take to be the late cases, areas are found on section to consist of fibrous tissue containing larger and smaller cysts. I have the head of one femur which consists of little else than dead bone and marrow, and this specimen is interpreted as coming from a comparatively recent case.

Various observers have noted the presence of cysts of the bone in this type of arthritis, but have not attached much importance to them. I believe that careful search will always reveal them, and that their presence can often be detected in the *x*-ray plate.

All the changes in the joint tissue probably result from the primary necrosis. They are principally as follows: New bone is laid down about the necrotic areas, but especially in the region immediately beneath the articular cartilage, as if to wall them off from the joint. This results in a layer of dense bone immediately beneath the cartilage—"eburnation." New bone is also laid down at the periphery of the joint cartilage, giving rise to the spurring and lipping so characteristic of the disease. The joint cartilage becomes calcified, and then wears away, leaving the underlying bone bare. This bone then becomes polished and ivory like, and grooved in the line of joint motion.

The synovial membrane, with any form of irritation, becomes thickened and villous. One does not see the succulent, lymphoid synovial membrane of the first type of arthritis, but a loose-meshed fibrous tissue containing more or less fat. These joints are often called dry, because they creak and grate on motion, but often they contain free fluid.

As the result of the bone formation, and of the disappearance of the cartilage, the ends of the bones become more or less distorted. They no longer fit, and their bearing surfaces are rough. The joint is a damaged machine, and, although the bone ends are not united either by fibrous tissue or by bone, a partial ankylosis, or interference with motion, re-

*Ely, Leonard W., and Cowan, John Francis: Bone and Joint Studies, I, Stanford University, California, 1916. Published by the university.

suits. Bony union, however, may occur in the spine.

Symptomatology.—The symptoms are those of a low-grade chronic arthritis. As a rule the pain is not as great as in an arthritis of the first type, and practically never are the symptoms acute. The sensitiveness to pressure, so often seen in the first type, is absent. The deformity is not as great. Muscular spasm and muscular atrophy may be present but are not so prominent a feature. The average age is greater. The patient is usually elderly, and the disease never occurs before the third decade of life. The joint creaks and grates on motion. Arterial sclerosis is a frequent accompaniment. Evidences of decay about the roots of the teeth are present, or vacant spaces indicate previous alveolar infection that has necessitated the extraction of the teeth. The anatomical changes of this form of arthritis are permanent, and a badly damaged joint will often cause symptoms long after the cause of the damage has disappeared.

When the disease occurs in the spine it usually manifests itself by pain referred to the region from which come sensory impulses over the nerves entering the cord at the same level as do those of the diseased joints. The pain is thus a true referred pain, and is not caused, as is popularly supposed, by any pressure on the spinal nerves as they emerge from the foramina. This class of cases is usually diagnosed as sciatica, lumbago, brachial neuritis, radiculitis, myalgia, fibrositis, etc., but any obscurity is easily cleared by a Roentgen picture of the spine, which will show the characteristic lipping and spurring of the vertebral bodies.

When it occurs in the spine the disease is usually more or less widespread, and several bodies will show the lipping. Elsewhere, although the symptoms may be confined to one joint, radiograms of other joints will often show in them also the characteristic changes.

Diagnosis.—The patient is usually middle-aged or elderly, and presents evidence of alveolar infection about the roots of his teeth. Films of his jaws show small abscess cavities. The muscular atrophy, increase of local temperature, muscular spasm, deformity, and swelling of the soft parts, common in an arthritis of the first type, are usually absent. The joint may possess a considerable range of painless motion, and usually creaks and grates. With a little practice one can differentiate the two types fairly well by a physical examination, but the diagnosis can be made absolute by the Roentgen rays. The film will show the new bone at the lines of insertion of the capsule—the so-called lipping and spurring, even when evidences of bone absorption are marked in the heads of the bones. There may be some cause for confusion in the finger joints, for here bone absorption dominates the picture, but in an arthritis of the second type the terminal interphalangeal joints are the ones to be involved, rather than the proximal interphalangeal and the metacarpophalangeal joints, as in type I. The terminal phalanges are in semiflexion and lateral deviation.

Treatment.—The first indication is to remove the focus of infection from about the roots of the teeth. If this be done early the pain may subside entirely, and the joint may return to a state approaching normal, though it must always be remembered that the anatomical changes are permanent and will never disappear. Even in more advanced cases extraction of the teeth is usually followed by an improvement, and the patient may get along in comfort with his damaged machine, as one may go slowly over good roads on the level with a rickety motor car, but the distorted joint is always vulnerable to sprains and will give trouble when it is used much.

The pain is best treated by heat in some form, perhaps reinforced by hydrotherapy. Dry heat will usually give the best results. When the disease is in the joints of the extremities, the so-called Bier treatment, passive congestion, often makes the patient more comfortable. For some unknown reason I have seen patients improve after the injection of a foreign protein.

The above remarks are not founded upon a few weeks' observation, nor are they evolved from my inner consciousness by abstract theory. The ideas are quite simple of comprehension, and, with a little practice, can be easily employed, but it seems to me that when anyone starts to treat a joint, he bids good-by to his intelligence and his judgment. No treatment is too fantastic to repel, and to this day the medical ward of the usual hospital reeks with oil of wintergreen. As far as its effects on arthritis goes, oil of wintergreen applied to the wall paper is probably just as useful as applied to the skin.

Perhaps the most pathetic delusion in treatment is the dietetic. The pendulum swings back and forth, first meat free and then carbohydrate free. At present, harking back to the old Salisbury diet of 40 years ago, the latter seems to be the more popular. Diet, of course, has a very real importance in the treatment of an arthritis caused by an infection in the tonsil or at the roots of the teeth, for anything which disturbed the digestion would quite naturally make the infection more active. Other than this, diet plays no part. When one's knowledge of a joint is confined to its external appearance, one can easily be fooled by pseudoscientific camouflage, but if one will take the trouble to cut these joints up, one will often be compelled to admit that one does not know, but never that the extensive bone and joint changes are caused by too much potatoes and bread, and can be cured by eating less of them.

TREATMENT OF CASES OF ULCERATIVE COLITIS.

By ANTHONY BASSLER, M.D.,
NEW YORK.

THE purpose here is to present matters of etiology and diagnosis, the employment of diet, the value of transduodenal lavage and dye solutions, and instances in which these had been employed.

Leaving out of consideration ulcerated colonic conditions due to tuberculous, syphilitic, amebic and *B. dysentericus* infections, there still remains what in practice represents the larger proportion of cases the etiology of which has never been clearly settled upon. Perusal of the medical records following the Civil and Spanish-American wars shows that many of such cases existed for years. Unfortunately in the first war little worth the while was known of these conditions, but in the later war better work was done in investigating these states of the lower small and the large bowel. Since 1916 there have been a number of such disorders among the World War soldiers who are now in civil work, and these have been added to by people who have lived in the East (Asia, Philippines, India, etc.) either as tourists or workers in missionary and other fields. Added to these are not a few, sometimes inhabitants of the northern States, but most often those of the South, who have developed the condition. Thus the incidence of this disorder is not so uncommon. Rather uniformly the cases are characterized by long continuance of the condition and rather hopeless results from the ordinary methods of treatment, namely rest, simple dieting, castor oil, opium, lead, bismuth, and other medicaments to which "tincture of time and esence of patience" do not seem to be sufficiently significant factors for results.

Up to the present, 92 such cases have been seen by me in private practice. These range over 8 years of time and occur in 9,500 records, showing an occurrence of .095 per cent. of all cases seen. It is probable that this percentage is fallacious as regards all gastrointestinal cases met with, because most of my cases are intestinal disorders rather than preponderately gastric and in this sense the percentage may be higher than occurs in the average way. On the other hand many such cases occur among the poorer people and thus would be met with in clinic and hospital practice, and, because of the writings of Gant and others, they were considered surgical and treated in that way rather than occurring in a medical practice. Thirty-seven cases have been seen by me in which irrigation methods following cecostomy, apendicostomy, and ileostomy had been carried out, the condition being only symptomatically improved during the irrigations and frank symptoms returning after a few months or a year's time. These are not discussed in this article or included in the percentage offered above.

Catarrhal and simple ulcerative processes are met with in children and those of young and middle adult life. The ulcers are present in both the small and large intestine, but more numerously in the latter. The early lesions seen are minute, round ulcers with very slight undulating edges and confluence of several small ulcers may be seen when the conformation would be irregular. The very special feature of this lesion is its superficiality, for apparently it involves only the mucosa and generally not too much depth in it. This probably accounts for the long-standing of the disorder without cicatricial formation, which may occur if the mucosa is involved to the basement membrane. There is usually much congestion of the bowel seen by proctoscope, tendency to bleed, irritability, and often a diminution in caliber, probably due to round-cell infiltration of the gut wall. Of course, diarrhea, fluid stools with blood, mucus, and pus, with generally a reduced state of body represent the common clinical picture seen.

Careful laboratory work in most of these continues to confirm my report made on four cases, namely that the inflecting organism is probably a *B. coli communis*. These can gain the tissue (submucosal infection of Adami) and flagella are present in many of the infecting forms met with. Injected into the peritoneal cavity of rabbits, guinea pigs and cats the organism is fatal in about four days, one of the latter, however, living to the ninety-third day. It is definitely clear that this *B. coli* is more definite pathologically than the usual forms of *B. coli* met with in normal human and animal intestinal tracts. It can be proven that serums from these cases agglutinize much higher dilutions than from innocent forms. This organism does not correspond to the Shiga or the mannite fermenting types, yet they also are not possible of biological differentiation from ordinary forms of *B. Coli*. Either they are definite organisms of the *B. coli* group or a *B. coli* of high pyogenic virulence, strongly hemiparasitic in nature, and from which the aggressive production is marked and against which the body in susceptible individuals fails to resist local tissue infection. I have ventured a designation of it as *B. pseudo-dysentericus coli*. In the study of scrapings from the lesions and study of the gut contents it is probable that other denizens of the gut may act specifically or symbiotically with them. Among such may prominently be mentioned

the *B. acrogenes capsulatus*, *B. pyocyanus*, and *Streptococcus fecalis*.

Diet.—Various types of diet have been employed, and in the majority no definite type of diet seems especially helpful. In the study of the records, however, two features in dieting have given service in many. One is a diet high in protein, and the second is (even with the diarrheic condition) to consider the patient as constipated and use anti-constipation additions. The high protein diet itself has often reduced the irritation in the gut without further treatment, and the same may be said of the anticonstipation diet which results, instead of in more movements, in the cleansing of the canal and fewer movements, and those of better character, during the course of twenty-four hours. Types of such diets are the following:

High Protein Diet.—The diet is a temporary one. Take mostly meats—all forms of beef, with the exception of cuts from the shoulder, kidneys, and liver. The same pertains to lamb. These meats should be fresh and taken in a broiled or roasted state. Mutton is permissible but no pork nor veal.

You may take any kind of fish cooked as above, and to which boiled is added, with the exception of shad roe and shell fish.

You may eat eggs in any form.

Any form of cooked, fresh vegetables that are green, such as spinach, beet tops, celery, etc., and any of the salads with French dressing very low in vinegar, may be taken.

Butter and whole milk are allowed, together with any form of simple cheese of the cream variety, such as Philadelphia or Neufchatel.

Eat as much gelatine foods as possible.

Oatmeal and rolled oats are allowed.

You may have bread or crackers made of gluten or rye flour.

Lentils and dried peas are permissible.

There is no objection to an occasional orange, pineapple, or strawberries.

The best drink for you is chocolate or cocoa.

All kinds of fermented milks may be taken—such as kumyss, matzoon, etc.

Anticonstipation Diet.—Measures to encourage your bowels to move in a normal way are the following:

Begin by taking three of the bran gems during the course of the day, and if you cannot get them, you may take in place of them a good-sized dish of Pettijohn bran, or from one to two tablespoonfuls of wheat bran mixed with oatmeal or shredded wheat biscuit for breakfast.

Bran gems: Mix 2 cups of bran, 1 cup of flour, 1 teaspoonful of soda, 1 teaspoonful baking powder, and 1 teaspoonful salt together. Add two-thirds cup of molasses. Add buttermilk enough to make a stiff batter. Melt 1 teaspoonful each of butter and lard together and add last. Bake in buttered muffin pans, in slow oven, for about 45 minutes. Note: A few seeded raisins may be added.

If the above does not move your bowels, retain the bran method which you are employing, and as an additional method take a dish of stewed prunes cooked with milk, sugar or honey, or molasses, at the evening meal or before retiring.

If the foregoing two methods are not efficient, take the prunes at the evening meal and a tablespoonful of petroleum jelly, or vaseline, before retiring. With the institution of this you are to take from three to six glasses of water during the course of the day, in the interval between meals, on arising and before retiring.

If then your bowels are not moving, add a few senna leaves to the prunes which you are taking, these being put in at the time of stewing.

If still your bowels do not move, drop the use of the bran, both in the biscuits and at breakfast, and substitute a handful or ½ oz. of finely cut agar-agar, eaten with cream and milk sugar at breakfast—this may be mixed with a cereal, but not cooked with it.

The foregoing method you should follow by beginning with the first and adding one thing after the other until the desired result is accomplished. Do not become alarmed if your bowels do not move in the beginning, or if a day goes by during the time you are on the above additions.

When active irrigation is being carried on, the fats are largely increased for their constructive properties, and sometimes constructive tissues.

Values of lavage of the intestine. As is well known various forms of enemata with different solutions, have been employed in the cases. As a rule, however, all such procedures have not been helpful and often distinct harm is done. It seems warranted to state that if the bowel cannot be irrigated from above, such as by the duodenal tube, the intestinal tube of Einhorn,[2] or by operation in which an opening into the intestine is made and catheter irrigation through it, it had best not be irrigated at all. This rule follows so uniformly throughout the cases I have seen that it is a matter of importance, and I have tried the enemata method in some of my own cases and feel convinced of its non-value.

Einhorn[3] has just reported his second successful case in which the intestinal tube was used with solutions of calcium carbonate, 0.5 to 1000 c.c. of water, then 1.0 to 1500 c.c. and 15 drops of ichthyol in the latter part of the drip, and for 1 week, 2 oz. of 1 per cent. mercurochrome (220). Irrigations with the calcium carbonate solution were conducted twice a day during the active treatment. As to the use of the intestinal tube, I am not familiar with it and there is no doubt if involvement of mucosa high in the ileum is not present and the disadvantage of wearing the tube through the active treatment and its removal is not a feature, it offers much worth the while. My own experience is that many of these cases must be irrigated for months and thus its use does not appear practical from that standpoint. However, the duodenal tube method should supplant the operations for irrigations, especially since many of those treated by operations are improved only as long as irrigations are kept up, and when the fistula is closed, the reperformance of operation for the original purpose is not fair to the patient, especially when the results by duodenal or intestinal tube are every bit as efficient and can easily be resumed at any time.

The irrigations practised by me are by use of the Jutte tube which gains entrance into the duodenum in the average person in about fifteen minutes, and while any of the many forms of duodenal tubes can be used successfully, for clinical work the speed of gaining the duodenum is a factor of importance. The main solution used is a hypertonic one of 9 grams each of sodium sulphate and sodium chloride in 1000 c.c. of water delivered at 105° F. Where the *B. pyocyaneus* or *Streptococcus viridans* figures in the infection of the gastroenteric tract the treatment is preceded by a stomach lavage of simple solution. When the tip of the duodenal tube is in the duodenum (as judged by fluoroscopic observation rather than by aspiration), the irrigation is run into the duodenum and this flushes through in usually from 30 to 90 minutes when practically all of the solution is discharged from the rectum. There may be a second or third alvine discharge

quickly following after the first outpouring, and generally the effect of the solution is over in about 2 hours time. This is conducted each day until the rectal mucosa shows distinct improvement, and then less frequently. When the patient has fever, looks septic, or has much irritative rash from the intestine, the twenty-four hour interval is kept up until these also materially improve. Where an operative fistula exists no effort is made to irrigate through it.

Of much interest in this connection is the employment of various dyes to beneficially effect the bacteriology of the intestinal canal. Influenced by the experiments of Churchman[4] gentian violet has been added to the hypertonic solution in strength of from 0.3 to 0.75 grams per 1000 c.c. Gentian violet has a somewhat selective action on most all gram positive organisms, and since the control of the element of mixed infection is important for permanent benefit and the *B. acrogenes capsulatus*, streptococcus viridans and fecalis are all gram positive organisms, the use of this die is a valuable adjunct. With the use of gentian violet it has been impossible to prove whether or not a bactericidal effect is produced on the intestinal organisms. I am inclined to believe it does take place because culture experiments prove this rather conclusively and clinically the cases do better when the dye is employed. What is interesting with this die, as well as mercurochrome 220 and acriflavine, is that staining of the mucosa cannot be demonstrated by proctoscopic examinations. The dye comes through in the discharge from the bowel much altered in the intensity of its color. These dyes do their depths of staining when thrown into limited areas, such as joints, ureters, empyema sacs, etc., but when introduced into the limited rectal canal for instance no staining of the tissue is observed, in this way also corresponding to the lack of staining effects of the inorganic silver salts in the intestine. This may be due to the large amount of bacteria the dye comes in contact with in the intestinal contents in that way vitiating it too quickly for it to be intense enough to stain the mucosa in an apparent way. With the introduction of mercurochrome 220, which is believed to be non-toxic, it looked as though this would be a valuable asset to the irrigation solution or to be used separately. It is probable that the small amount of 2 oz. of a 1 per cent. solution, such as Einhorn employed, would be well tolerated, especially when introduced alone. My first case in which this was employed was one that had been irrigated with a simple hypertonic solution for 7 days and was symptomatically improving. On the eighth day 10 oz. of a 1 per cent. solution was introduced through the duodenal tube 2½ hours after the hypertonic solution and when it had thoroughly cleared the tract. The result was apparent in a few hours in the discharge of almost total blood, marked abdominal distress, fever and intense irritability of the colon that lasted 11 days. It is possible that my initial case had an idiosyncrasy to mercurochrome producing a marked reaction, that I employed too much of the dye, or should not have followed it after the hypertonic solution. Since that time I have employed it with success in six cases in weaker dilution, but to-day experiences from results have made me resume the gentian violet which seems safer to use in the larger quantities required to influence intestinal conditions. In the last years as an addition to the gentian violet in irrigations, I have employed gentian violet in enteric coated pills, each containing 0.016, these being taken after meals. It is probable that these have an additional value. Acriflavine in pill form also works to advantage on the *B. coli*.

There comes a time in these cases (usually after the sixth week) when active treatment in bed seems no longer required. The improvement is so marked, generally with gain in weight and strength, that the case logically becomes ambulatory. At this time weekly or biweekly irrigations may be kept up, and the diet as mentioned becomes important. With the patient under active treatment in the sanitarium or hospital the diet is not important, the usual soft diet of ample calories meeting all the indications. But now the high protein diet, with or without the constipation additions comes to the fore and it is incumbent on the patient to follow these rigidly. The gentian violet or acriflavine pills, salol, with or without bismuth may be employed, and as much physical rest as possible insisted upon. The use of active cultures of *B. acidophilus* kept up in large doses until the *B. coli* are definitely reduced, and then in smaller amounts seems in order for several more weeks of observation. The importance of body chilling, especially of the abdomen, should be guarded against, and until the irritability of the intestinal mucosa has subsided substantially there is no better item of treatment than that the patient should live in the open. Those who can afford it, in my experience, do better in southern California than elsewhere. Several have gone there and secured employment in the larger cities and have remained steadily free of intestinal symptoms.

Up to three years ago there was considerable work done in my cases with the use of antidysenteric serums and subcutaneous administration of *B. coli* (autogenous). A few were apparently benefited in small degree by the use of the serum, but in none could this definitely be judged as apart from what was being accomplished by the other treatment. The same was true in a general way with the *B. coli* vaccines, although in nine of the early cases it seemed as if some beneficial effects were being accomplished. This, however, was so trivial and irregularly met with that both the vaccine and the serum were discontinued and the results are apparently quite as good as with them.

Germans Teaching Radiology in Spain.—Three Teutonic radiologists, Friedrich of Freiburg, Chaoul of Munich, and Wernekros of Berlin, are conducting a course of radiology in the University of Granada, which is free to the medical profession. The fact that instruction is given in the French language only is probably a matter of teaching efficiency, although it may be done also to anticipate the criticism of German propaganda. The Germans naturally brought their own apparatus along.—*La Presse Médicale.*

SYNERGISTIC ANALGESIA;

ITS ADMINISTRATION IN OPERATIVE GYNECOLOGY.

By J. M. RECTOR, M.D.,

JERSEY CITY, N. J.

WHENEVER study and research, or the successful application of new ideas, are applied or followed in clinical work and there appears an advancement over existing procedures, one can but awaken to the possibility and watch with keen thought all that has been accomplished and be prepared to participate and advance when the betterment is near at hand.

New facts emanate constantly from the laboratories of the fundamental sciences; some are of a practical purpose while others are achievements destined to be potential in the progress and advancements of the future. The great mass of recent progress has been the result of biological study and research. Future success will depend upon its intimate knowledge and its practical application to clinical work.

Anesthesia has made surgery possible and while its principles have been made use of in many ways and under different forms and applications, it has always been a source of worry and anxiety to the surgeon. Every surgeon prefers his own form of usage or application and since no two surgeons agree in its mode of application, it is a paramount truth that general satisfaction is wanting, while it is only the brilliancy of an advocate that will popularize an individual method. General anesthesia with its many modifications, various mixtures, and the great number of instruments for its direct or indirect application makes one wonder whether the study and advancements are at all satisfactory and that some form, either more simple or more safe, is not the possible solution of the problem.

The recent researches of Dr. James T. Gwathmey tend to show that synergistic analgesia is an advance over direct anesthesia, in that the dangers and complications, the disagreeable effects incident upon the giving, and the post anesthesia results are lessened, if not completely done away with.

The basic idea depends upon the analgesic effect of magnesium sulphate in combinations with morphine sulphate to which may be added ether, chloretone, paraldehyde, cannabis indica or other drugs of the same class.

Gwathmey tells us that, "with inhalation anesthesia alone, the lack of relaxation and the after-effects of nausea, vomiting, and gas pains, are induced by the morphine. By the addition of magnesium sulphate to the preliminary morphine medication, a better relaxation is obtained and the nausea, vomiting, and gas pains are much reduced, if not entirely eliminated. When no allowance is made by the anesthetist and when anesthesia is superimposed upon the state induced by preliminary medication, the patient is immediately plunged into the danger zone and possibly into a condition of shock from the inhalation anesthetic."

"The action of the magnesium sulphate is to hold the morphine sulphate in contact alone, or that assumption may be made that each of these agents affects in different ways the same part of the central nerve system, or has an affinity for special nerves or centers, and on the whole the combined result is safer and more powerful than that of one when used alone."

When one considers how often there is a dread fear of the patient for the taking of an anesthetic; the choking, coughing, and sense of strangulation with its irritable effect upon the mucous membrane of the respiratory tract; the stage of excitation with its varying degrees of laughing, shouting, crying, twisting, turning, and violent struggling; the hours of nausea and vomiting consequent upon the completion of the operative procedures and the withdrawal of the anesthetic, he may contrast this picture with one of absolute quiet and rest, a gradual loss of tactile sense followed by drowsiness and total ignorance of time of operative procedure; at times asleep and unconscious while still in bed; no knowledge of having been removed from ward or room to operation suite, passing through a major operation with no excitation or fear of entrance into a danger zone, with little or no change in blood pressure, pulse rate, or respiratory sequence; the return to bed in ward or room, the placing of a pillow beneath the head and the patient resting quietly with no excitation or depression until return to the normal has been accomplished.

In general, I have noted the willingness of patients to accede to my request for the use of analgesia. There have been no material conditions in its application when my directions have been carefully and intelligently followed. In none of these cases has there been excitation or depression, no idiosyncrasy to magnesium sulphate, no harmful effects upon the respiratory center, and no laxative or irritant effect upon the bowel. Morphine sulphate, chloretone, paraldehyde, deodorized tincture of opium, and cannabis indica have been used alone and in combination, given by mouth, per rectum, and by hypodermic. Consciousness was generally present, loss of tactile sensation usually began to show itself about one hour after the giving of the synergistic analgesic combinations. In most instances this loss of sensation began at the feet and extended upward, the patient reporting the limbs felt heavy, and while they could move them they did not feel the pressure of mattress or bed clothes. Analgesia would increase until the patient would not feel the prick of a pin or the pinching of the skin. The patient was transferred at once to the first stage of inhalation anesthesia.

After the giving of a sigmoid instillation the patient was placed upon a carriage: if in ward, was removed to an adjacent room which was previously darkened, if in a private room, the shades were drawn and door closed. Light was excluded from the eyes by covering the face with dark colored mask, and the ears stuffed with cotton. An occasional attention was given to the patient until removed to operation room. As much noise as possible was avoided at all times. Orders and necessary conversation were given in low tone of voice.

At times the patients were semicomatose or sleeping, they could be aroused by shouting or talking in a very loud tone of voice and close to the ear, they could be moved from ward carriage to operating table, placed in Sims, Trendelenburg, or exaggerated lithotomy position without the slightest resistance or evidence of muscular rigidity. The usual operative drapings were accomplished and

the operation field prepared without disturbance, until towel clips were made to catch the skin, when reflex was aroused, and the patient winced. There was no complaint of pain and with clips in position the patient would become quiet. In routine, all vaginal work, including curettage, was performed without the use of an inhalation anesthetic, in many instances while operating within the vagina no one was at the head of the table, a junior would be occupied in taking blood pressure, counting pulse rate and respiration. I would often remove the ear plugs and carry on a conversation with the patient while my house gynecologist would be performing a curettage. It was not possible to open the peritoneal cavity without the use of an inhalation anesthetic. After entering the peritoneal cavity the inhalation was either discontinued or given until the patient had passed into the stage of automatic respiration, then to be stopped and only used again upon the return of muscular rigidity.

Shock was uniformly absent and at no time was there necessity for the administration of cardiac or respiratory stimulation. Postoperative pain did not appear in the great number of cases, and in those cases in which it did appear, it was greatly lessened and its continuance was a matter of a few hours only.

Excessive vomiting was present in two cases, and in both instances it began before operation, continued during operation, and lasted for several hours following its completion. Singultus was frequent during the first hour following the sigmoid instillation.

Novocain in one and two per cent. solutions was used for skin and abdominal wall, but was not found as satisfactory as the inhalation anesthetic. Nitrous oxide and oxygen were not used in any of my cases. The general technique herewith reported has been followed in 100 cases, the procedures differ materially from those heretofore reported by Dr. Gwathmey.

The preliminary preparation in all cases has been the same. The night before operation, two soap sud cleansing colonic enemas into the sigmoid were given one hour apart, *i.e.* 8 P. M. and 9 P. M., the patient going to toilet after each enema The morning of operation the patient was given two clear hot water enemas one hour apart, *i.e.* 5 A. M. and 6 A. M., the patient going to toilet after each enema. It is important that the entire rectum and sigmoid be cleansed of all bowel excrement. The ordinary 18-inch rectal tube was used.

The analgesia continued about two hours, while the return to the normal would vary from three to five hours. When an inhalation anesthetic was necessary ether alone or in combination was administered: *i.e.* chloroform ℥i, ether ℥iii, or a mixture of chloroform 2 c.c., ether 96 c.c., ethyl chloride 22 c.c., oil of orange ½ c.c.

Series 1.—Two hours before operation, 20 c.c. to 30 c.c. of a chemically pure 25 per cent. solution of magnesium sulphate made with distilled water, filtered, and sterilized, was injected slowly beneath one breast or divided equally in both breasts, taking care that the needle did not enter a vein. It is most important that nothing but a pure, clean and specially purified grade of magnesium sulphate be used. It must be freed not only from all mechanical dirt but also from chemical impurities. The preparation made by Squibb and so prepared was used by me. One hour before operation an hypodermic of morphia gr. ¼. One half hour before operation sigmoid instillation; ether ℥ii, paraldehyde ℥ii, olive oil ℥i. In giving the sigmoid instillation the patient was placed upon the left side, the buttocks slightly elevated. The medication was carried slowly into the bowel, through the 18-inch rectal tube, the tube was clamped and left in situ to be removed when the patient was placed upon the operating table. Fifteen minutes before operation, hypodermic of morphine gr. ⅛ and atrophine gr. 1/150. Chlorotone and fluid extract cannabis indica in varying doses were given by mouth.

All curettements were performed without inhalations. Mucous vomitus was occasional, postoperative pain only in operative area. Gas pains were not present. The patient did not require the continuous attention of a nurse. No period of excitation was present. Morphine sulphate was not given at any time following the return to bed.

Series 2.—In this series the sigmoid instillation of series 1 was omitted to determine the combined effect of the magnesium sulphate and morphia with the suppository of chloretone and cannabis indica. The patient felt the pain of the pin prick and pinching of the skin and while it was not necessary to use the inhalation for curettements, it was used for the dilatation of the os uteri. There was scant analgesia present during the abdominal work.

Series 3.—Two hours before operation 30 c.c. 25 per cent. solution of magnesium sulphate, morphine gr. ⅛, half in each breast. An hour and a half before operation rectal suppository (chloretone gr. xv., extract cannabis indica gr. ii). An hour and a quarter before operation sigmoid instillation (ether ℥ii, paraldehyde ℥ii, olive oil ℥i). Half an hour before operation morphine gr. ⅛, atropine gr. 1/150, hypodermically. Quarter of an hour morphine gr. ⅛, hypodermically.

The beneficial effect of this procedure was noted by the deeper analgesia, less rigidity of abdominal muscles, and a shorter period of inhalation anesthetic.

In series 1, 2, and 3 the site of election for hypodermocylsis beneath the breast or breasts and into muscle substance was chosen as the most advantageous locality, because of convenience and least amount of disturbance to the patient. Four cases were followed by an inflammatory reaction, but investigation showed the solution was faulty and directions as to its giving had not been complied with.

Chloretone and cannabis indica in the form of rectal suppository (series 2 and 3) gave better results than when given by mouth; analgesia was deeper, the abdominal muscles were less rigid, and the time of the inhalation anesthetic was shorter. The addition of morphine gr. ⅛ to the magnesium sulphate solution (series 3) was advantageous. There was no untoward result from the sigmoid instillation.

Series 7.—Two and one-half hours before operation, morphine gr. ⅛, and atropine gr. 1/150, hypodermically. Two hours before operation, sigmoid instillation (25 per cent. magnesium sulphate, ℥vi-℥vii; ether ℥i-½-℥ii; glucose ℥i-½; olive oil ℥i; de-

odorized tincture of opium mxx-xxx; powdered acacia, q.s. to make an emulsion).

It will be noted that the analgesic procedures were simplified by lessening the number of individual medications and increasing the ingredients of the instillation. At first the entire dose of morphine was given with the instillation but the patients complained for several minutes of a burning and stinging effect produced in the sigmoid; consequently half an hour before the giving of the instillation a hypodermic of ⅛ morphine and 1/150 atropine was administered.

This procedure was not satisfactory because of complaint in all cases, of postoperative pain in the operative area, mild form of gas pain, light analgesia, pronounced restlessness, and rigidity of the abdominal walls.

Series 11.—Two and one-half hours before operation, morphine gr. ⅛-¼, atropine gr. 1/150, hypodermically. Two hours before operation, sigmoid instillation, ℥xii, (25 per cent. magnesium sulphate, ℥vii; ether ℥i-½; glucose ℥i; paraldehyde ℥i-℥ii; olive oil ℥i; morphine gr. ¼; powdered acacia q.s. to make an emulsion).

In this procedure morphine was substituted, in the instillation, for the deodorized tincture of opium to overcome the complaint mentioned in the previous series. Series 4, 5, 6, 8, 9, and 10 have been purposely omitted, it being beyond the scope of this paper because of the length of the complete report.

This limited experience has been of sufficient value to convince me that analgesia is a vast improvement over the present form of anesthesia. The results I have obtained mark the beginning of an investigation, which will require much study and trial to perfect. There is no doubt that concomitant conditions and correlative circumstances will influence the combinations of choice in meeting the many pathological states. In some instances one technique appeared to be successful, while again a series of cases would present themselves which would show better results by making some material change in the analgesic combinations. Temperament and individuality influenced the results more than age, sex, or nationality. Acute diseases responded more quickly and the analgesia was more profound than when given in cases of long standing. The more careful the technique, the more successful the results. The inhalation anesthetic when given with the Flagg or Bennett inhaler was most satisfactory in that a better control could be exercised in the minimum amount necessary to produce unconsciousness, and abolish or control muscular rigidity. It was noted in all cases that the inhalation must be discontniued immediately upon the occurrence of muscular relaxation and loss of reflex sensation, as the patient would be plunged deeply into the danger zone, and the inhalation is not to be administered again until rigidity had reappeared.

Iron in Cancerous Anemia.—A. Robin and Bournigard state that the anemia of cancer patients is due to demineralization of iron in the blood and of the reserve iron of the tissues. The disintegrated iron may be found in the urine in double the normal amount. The anemia is due to inability to form new red cells to replace those which are destroyed.—*Bull. Méd.*

THE USE AND ABUSE OF LOCAL SUPPORT, ALSO MOTOR REDUCTION IN HUMAN READJUSTMENT OR ORTHOKINETICS.

By J. MADISON TAYLOR, A.B., M.D.,

PHILADELPHIA, PA.

PROFESSOR OF PHYSICAL THERAPEUTICS AND DIETETICS, MEDICAL DEPARTMENT, TEMPLE UNIVERSITY.

(*Concluded from page* 182.)

Resources of Support for Relaxed or Impaired Muscles.—The resources available for support of relaxed or impaired muscles have not yet come to be accorded the attention the topic deserves by internists, though perhaps they have by surgeons. Much can be learned from surgical literature where the findings are many, and but little from that of the internists; useful observations are often to be found, but scattered and incidental. The subject warrants systematic correlation. The utmost I can do is to offer such hints as may serve to impress the value of temporary reinforcements for disordered muscles, not only for themselves but as they influence functional relationships to the hollow and tubular viscera, notably the circulation, in particular of the splanchnic areas, and also of areas so rembte as oftentimes to suggest little bearing on the real causal agency.*

We may visualize the subject of support for relaxed or impaired muscles as of two major domains, during acute inflammatory and painful states, also for an injury and during the whole period of acute disability as, *e.g.* from poliomyelitis, following hemiplegia, also during as well as after rheumatism, gout, acute arthritis, following the infections, such as pneumonia, gonorrhea, tuberculosis, also in locomotor ataxia, neuritis, and a host of other states wherein local and painful disorders occur with more or less frequency.

A good working rule is to be prompt in placing a joint or limb at absolute rest during the period when it is acutely disordered or painfully affected, in order to secure the maximum position of advantage for functional repair. Directly at this point the caution should be emphasized that in even the most acute states due to infections, traumata, paresis, and—as the surgeons are now urging—in fractures and after amputation, the best ultimate results follow encouraging volitional exertion at the earliest suitable moment. Precisely what that moment shall be is specified by surgeons who speak from experience. When immobilization is continued beyond the period when it is actually needed, or when voluntary movements must be made, not only does the tone of the structures begin to fail, but the parts grow weaker (asthenic, adynamic). This disrepair oftentimes becomes permanent. Suffice it to say here that many contributions are rapidly accumulating in which warnings are sounded against "the curse of immobilization."

*One of the most suggestive and helpful of books was long ago contributed by Dr. Albert Abrams, entitled: "Splanchnic Neurasthenia or the Blues." In this the author presents a wealth of suggestions and recommendations in the recognition and relief of a large group of distressing maladies, somatogenic and psychogenic. Later researches by this author throw valuable light on making use of reflexes, the cardiac, abdominal, cerebral, and other, in his work, "Spondylotherapy." To this the reader is referred for specific information.

Now support is one thing and immobilization is another. The support may be complete for periods of time; these periods, however, must not be too protracted, otherwise function is reduced to an extent wholly indefensible. The question is being put by surgeons and often seriously opposed, as to whether protracted and complete immobilization is ever to be encouraged.

In respect to the use of support in complications, coming within the internist's domain, it is my personal judgment that—enormous as is the value of fixation of, say, a joint affected by rheumatism—more harm than good is likely to follow protracted immobilization unless the utmost judgment is used.

The functional competence of living beings depends (biokinetically) upon a right condition of tone in the muscles, tendons, fibrous structures which afford support to the organs. The term support as applicable to clinical problems is the sum of the effects of devices—natural or artificial—capable of helping a part to perform its normal functions safely and comfortably. Any artificial support should be used only for so long as absolutely necessary and should be frequently removed with a view of encouraging volitional control. A support for hernia may need to be used indefinitely, but the real objective is to use it only till a radical cure is affected. This cure may occasionally come about through natural repair, but much more certainly and economically through surgical repair.

The purpose of support is to amplify the power or puissance of structures deficient in tone and to enable these structures to regain tone through normal use—movement—through graded and particularized volitional training.

The topic deserves discussion from all aspects, indications for the support, the nature and character of the support needed, where and how it can be best applied, the objectives to be obtained, likewise comments from experience and observation with particular emphasis on the aid which support furnishes in the achievement of rehabilitation of power and hence of functional competence.

Warnings Necessary to Observe in Employing Immobilization.—The utmost vigilance must be practised in regulating the kind, amount, degree, and length of time immobilization shall be used. So important is this that many surgeons omit fixation in conditions wherein it has been used from time immemorial, among which are fractures. Surgical literature is full of such observations, recommendations, and warnings.

Perhaps it is sufficient to generalize thus: Fixation is only and solely of value to supply that degree, quality and continuity of local rest as shall prove sufficient to meet the actual requirements and no more. Just as soon as the primary or essential requirements are fulfilled, fixation should be limited or removed. Function performed makes, and when omitted unmakes, structure. The exercise of motor function is no exception. Indeed, it is well to err on the side of liberality in permitting and encouraging movement in such parts as it is permissible. Apparatus to afford support is for the sole purpose of encouraging the disabled parts to perform permissible motor function. Every encouragement must be given to voluntariness.

Devices for Reinforcing, supporting, or fixing painful, injured, inflamed, under-developed, overstressed, over-relaxed, seriously weakened, paretic, or deformed parts.—The legitimate purpose for using any supporting or locally resting device or measure is in order to fortify the impaired structures only until they are again enabled to do their own work in accord with design.

An essential adjuvant to the use of support is a confident encouragement devised to reawaken determination and whatever latent motor energies exist. This training in volition, or conspicuous purpose to perform can and should be begun while the suffering part is held at rest. Personal effort and expert guidance should begin just so soon as pain or inflammation subsides sufficiently. Passive acts done by the operator, guiding touches, pushes, directings, pullings, torsions, and the like, are desirable throughout treatment and with graded increments of force. Function makes, and equally remakes, structure provided there be enough good material present to begin on.

The first step in utilizing support is to rid the structures of any mechanical, spastic, or psychogenic restrictions to movement or of tonic spasm. This is most important. Muscles which are primarily weak or weakened by damage or partial paralysis (paresis) need assistance in development or by throwing the stronger ones out of commission and then encouraging the weaker ones. This can oftentimes be done by fixing the stronger ones. Often the stronger ones are in tonic spasm and these must be released.

Volition is the chief reliance, a teaching of the stronger muscles to relax when in tonic protective spasm. This can be effected by skillful touches, pressures, or spastic or over-tense groups, or by light concussions—alternating with omissions for two or three minutes. Use alternate tapping for one minute—omitting one or two minutes, tapping again, total about three or four times, usually suffices. If insufficient use gentle pressures. Follow at once by voluntary movements. Isolation of stronger muscles is said to be accomplished by injections of 80 per cent. alcohol into the nerve supply of the stronger group, thereby inducing a temporary paresis.

Also motor equipoise can materially be helped by slow voluntary energizing through performing movements of each alternate group, chiefly of the adynamic group. Alternations of slow movements with rest are best. After these devices have been used, and as near an equipoise acquired as conditions permit, then the impaired group may need support to afford rest and aid nutrition. Expectant attention (psychic hypertension) may be felt in those muscles directly associated with the paretic group, inducing weariness and transferred spasticity; or there may be pain in those affected, or even tremor. A limb affected by tremor is sometimes temporarily relieved by fixation, especially in a hyperextended or hyperflexed attitude—the one which experience demonstrates to be best.

The first element of support is a suitable or compensatory attitude. This deserves attention. Here is a department of the fine arts and one in which it pays to become an adept. The acme of good home remediation and of good nursing is the placing of an ailing body in positions of ease, of advantage. Wher-

ever there is undue drag on a weakened or suffering part, that part should be adjusted so as to be comfortable. There may be no sensory disturbance to direct attention, but that is all the greater reason for discovering the need and supplying the deficit with promptitude and resourcefulness. Here we may merely mention some of the objects which, used with skill and tact, bring down blessings on the doer and raise the index of appreciation for vision and expertness:—Pillows, little ones well placed, pads of soft material under parts which experience stress, wedges of firm material under these pillows to give shape or extra carrying power, or under the mattress, as needed. Especially is a pad under the ankle of avail so that the heel may be raised and not compressed by resting its weight on the calcaneum, but to hang over. This small relief may cure an insomnia, a backache, headache, or other transferred stress. So of attitude readjustment in elbows, knees, hips, etc. The very best support to surface tissues is thin rubber tissues, devised by the late Morris Longstreth. A special rubber tissue is used and when fresh serves a number of purposes through its steadying action on the skin, subdermal structures, blood vessels, and sweat glands.

The niceties of using rubber tissue were taught me by the enthusiastic "discoverer." Bandages and splints, familiar as they are, can supply exceedingly artistic opportunities. As a young assistant to that master in medicine, Weir Mitchell, I gained a large credit for cure of a peculiarly favorite patient who came under my care during his absence of some weeks, and who developed acute rheumatism involving hands, arms, and legs at once. The pain and tenderness were appalling and unrelievable till late one night I broke up a pasteboard box, got rolls of cotton and lightly bandaged and splinted the arms and legs. Whereupon the medicines worked—or Morpheus, the God of Sleep, arrived.

Severe pain must be relieved. Well adapted support will do more in acute arthritism than "mandragora or all the drowsy poppies of the East." Splints are familiar tools, but how often does the internist use them except for a fracture or sprain? They render equal service in a number of exigencies, but *must not be tightly placed.*

Sand bags, especially long ones with a fixed trough or so-called "Physick's long splint," laterally from axilla to *and beyond* the ankle are of paramount service in painful and inflammatory conditions; a turn of a bandage may also be used to steady.

As a supporting appliance the resources of adhesive plaster reach the heights of a wonder worker. Among the particular adaptabilities of Z. O. plaster are: to a hanging belly, to splanchnic circulatory disorders, in pleurisy, pleurodynia, pneumonia, in acutely painful states of almost any situation or degree, injuries, bruises, spasmodic states, fibromyositis of the abdominal parieties, contusions, blisters—laid directly on and widely embracing the bleb, slits being made to let out the serum—also to be placed over strong iodine or other escharotic or medicament to be absorbed, also over muscles after severe manipulation. One of the most valued uses of Z. O. plaster is to place *strips over a constricting, contractured scar,* in order to be able to seize and lift the surface, to manipulate and free the adhesions, to remove the compressing action on blood vessels and nerves. Indeed, there is no end to the uses of Z. O. plaster as a supporting, also compressing, instrument. Straps for pleurisy should be broad, put on during full expiration and to nearly encircle the whole torso.*

Plaster of paris bandages deserve mention; also those of other similar substances. Then there are a number of useful forms of supporting devices, such as trusses, testicle supports, and the like. We now come to a large and important domain:

Abdominal Supports, Belts, Girdles, Cuirasses, Corsets.—Some of these do far more harm than good; this is invariably the case if used too tightly or for too long. The best supporting belt to serve as a type is that of Morris Longstreth, described at length elsewhere. This is the ideal belt, hence a brief description will suffice to exhibit the major desiderata to which any other device should conform. This consists of a *non-elastic* girdle, five inches wide, of cotton horse-girthing encircling the hips, from the anterior superior spine of the ilium to the external trochanter, reinforced in front with three whalebones, one vertical and two at the angle of Poupart's ligament, to keep it from "buckling up," fixed by four strong one-inch tapes and buckles behind, worn over the undershirt, kept down to place by nicety in adjustment and *not* by perineal bands. Successful adjustment depends on keeping the lower tape (of the four) just firmly placed and each of the other three a little *less* tight, till the upper one is *least* tight. Otherwise the belt will "ride up" and get about the small of the back and serve no good purpose, only exert harmful compression. It takes from two to three weeks to get the hang of this belt; then its admirable qualities will demonstrate themselves. Of course any belt or supporting girdle should be put on while the patient is lying on the back.

All attempts at "fitting" abdominal supporters by cuts or tucks are of dubious value. The sides of a good belt, or abdominal girdle, should be *parallel.* Only when made thus do we get that nicety of support by which the lines of force are distributed as needed to raise the viscera, to grip the big supporting structures of the hips, and to do the lift required.

As to corsets, the female of the species demands that they shall be worn, whether needed or not. They seldom serve any good purpose except to gratify a whim of the wearer. Ordinary corsets so constrict the abdomen as to produce a *downward* compression. The now fashionable "straight front" corset can be made to compress the lower abdomen to any desired degree. Too often *when once worn they are always worn* and the vigor of the structures compressed are permanently impaired. "The last state" of that wearer thus becoming "worse than the first."

*Doubtless every clinician cherishes the conviction that he knows all about the uses of Z. O. plaster—so did I till I had as a patient for some years till his death, an old friend who was a veritable Lazarus for real, inexplicable heartrending, kaleidoscopic disorders and diseases. As an artist of the first class in the Z. O. he had no peer, causing it to work miracles of efficiency direct and indirect. This included inanimate as well as animate structures. Had manufacturers of this plaster learned a tenth part as much from him as myself they would have paid him handsomely to demonstrate.

Then there are special shoes to afford support to so-called "broken" or weak, longitudinal arches. These give comfort at first, but inevitably bring almost the same destruction of function in the arch springs and plantar muscles as the corset does in the abdominal muscles.

The radical cure of flat foot is muscle training to regain the prehensile power of the foot.* Here again a device of Morris Longstreth called an "elevation" is the best device, described in the paper cited above.

Suspension or Head Traction.—The head often needs support when the neck muscles are at fault, or when some weakness exists in the arthroses of the cervical spine. Various forms are employed, but they could be much improved. I devised one for a lady whose neck was paretic after a trauma, of light aluminum tapes crossing over at the head of the seventh cervical, by movable rivet, one strip to curve by each side of the head, above the ear, then on a movable pivot or pin, to join an encircling band around the forehead and occiput, and held under the arms by tapes. This can be covered and made into a tasteful bonnet for a woman and acts admirably.

The jury mast is a familiar and helpful device. Some are attached to the cuirass, others to a chair. Of great efficacy is the sling, to support a limb from an overhead position, to relieve the stress of dependency or to raise a part in order to encourage the draining away of stagnated fluids. Suspension of a part is often of great comfort and when least expected. Graduated suspension used for tabes possesses greater value than has been accredited and deserves further demonstrations.

Traction also is of great efficacy and comfort in neuritis, tonic protective spasm, joint involvement, to relax structures forced into cramped positions. Any person who is long confined to bed, and especially to a fixed position, even though it be partial and temporary, is grateful for suggestions as to changes in attitudes, and especially for temporary fixation to support constrained parts.†

Supporting devices are coming into increasing popularity for a number of conditions not heretofore recognized as needing them. This is especially true of conditions of the lungs, heart, great vessels, and many displacements of the abdominal organs for which they had not been considered.

The heart and liver are often found to be displaced downward and need support. So of the lungs, which are not often ptotic but demand fixation for a number of reasons over and above the immobilization of the pleura. Diaphragmatic and pleuritic involvements, sometimes mediastinal, are relieved by abdominal fixation. So of emphysema, many asthmatic conditions are greatly relieved by fixation about the diaphragm which aids the expiratory efforts. This is an excellent means of repairing many, or clinically curing some, such disabilities, acute but especially the chronic. As to thoracic faults, use of support for the heart and lungs is often, as it is in enteroptotic disorders, one to supplement developmental measures. *Support* is a great aid to this, *while muscle training* is being performed.

*See article by the author on "The Significance of Foot Troubles and Deformities," *New York Medical Journal*, November 1, 1919.

†See article by author, "Arm Pains, Coordinated Occupation Neurosis, etc., *Interna. Clinics*, March, 1921.

The circumference of the thorax should in every one be at least two or three inches greater than that of the abdomen, in order to be safe or functionally competent throughout. Blood ptosis is a serious matter. It is seen at its simplest in fainting. Anyone who faints is then deficient in vascular tone, which may be temporary or protracted. Splanchnic vascular relaxation has been referred to. It is a highly significant condition, of far-reaching force.

Among the most familiar forms of ptosis are those of the abdominal organs, including the liver and stomach, colon, also the kidneys, and the genitourinary organs, all the way down to the uterus, adnexa, and the rectal structures. In enteroptosis there is also the peril of kinks, torsions, irregularities, obstructions. Mechanical devices for replacing or sustaining displaced viscera are notoriously problematical. The difficulties are many; the first is to replace dependent organs which are usually resistent, as by adhesions. It is recommended to cultivate omental fat to act as a cushion. One observer has called attention to "our little supporting balloons," sections of intestines distended by gas. At best all these are unreliable. The most promising method of visceral replacement is by reversal of attitude, head hanging or hip raising. These unnatural attitudes can be maintained only for short periods. Even then when coils of intestines are pushed up, in or near to where they belong, the problem of retaining them is serious and discouraging. Certain experts in muscle training go so far as to teach a series of movements which include standing on the head. I have seen their demonstrations and was at first amazed at the endurance which could be achieved in this reversed verticality after the pupil had practised it for some weeks. Undoubtedly good results are thus obtained. The measure deserves open-minded attention. Individuals who have good hearts and are free from degenerative changes in their arteries, seem to suffer no discomfort from standing on their heads repeatedly, and for many minutes at a time. Flushing of face soon ceases to be noticeable. Prejudices against this exploit are hard to overcome, yet it well deserves trial, especially in coloptosis. I have for years made extensive attempts at manipulation of the intestines through various procedures, including subdermal tractions; a bit of Z. O. plaster put on the surface helps mightily, and in many instances where there is no active inflammation present, attended with distinct success.*

Relaxed pendulous bellies need support, but only until their defective walls can be restored by musculotendinous development. Suitable supporting girdles furnish aid while the natural supports are being rehabilitated. *Colon irrigation while in the knee-chest attitude* supplies an upward hydraulic push of much efficacy.

Supplying this element of support tends to relieve promptly many asthenias, adynamias, blood ptoses, many backaches, headaches, latent acquired deformities, intraarticular tensions, in the vertebral, sacroiliac and other junctures or synchrondoses; so also to economize repair of energy in sleeplessness, nervousness, distresses, pains.

The *truss* deserves passing mention, especially

*See paper by author: "Visceral Stasis, Mechanical Obstructions and Their Effects Relievable by Rational Measures," *New York Medical Journal*, July 31, 1915.

those for diastasis of the abdominal recti. Also the head traction device, known as "the jury mast," is invaluable for fixation of the head. This is an efficient instrument for neck traction in case of disorders of the cervical and upper thoracic vertebræ; also in many forms of disability wherein the structures of the spinal column, or associated parts, are overstressed or contractured. This often occurs among the after-effects of poliomyelitis and of diphtheria; also in conditions of retarded growth, the secondary effects of fibromyositis, in relaxation of joints, and in a host of disorders.

Periarthric structures may also need support, apparatus, or reinforcement, to prevent excessive movements, and to aid in performing movements involving mobility, flexibility, pliancy. Full movability of joints and tendons is essential to integrity of motor and static function. Full flexibility of muscles is necessary to maintain motor competence, prompt response to volition, transference of motor stimuli, to secure full reaction times, and to permit and encourage the ebb and flow of fluids and nerve impulses.

Normal mobility of the backbone is essential not only to the function of the vertebral supports, but also to maintain the integrity of the spinal subcenters, normal innervation through the lateral branches of the spinal nerves, rami communicantes, and to encourage circulatory rhythms.

Rigidities and loss of elasticity or muscle tone are common in young as well as old, especially after injuries (fractures, sprains) or in certain diseases, *e.g.* fibromyositis, arthritism, and scar tissue formation. They may also result from periods of enforced sedentary life, long convalescence, chronic irritation, and overstress due to local tonic spasm or vagotony. Rigidities are especially hurtful to function in structures of the chest. The limitations of movement impair respiration and impede cardiovascular action and lymph propulsion. For example, in muscles of the neck protracted rigidities cause interference with passage of body fluids to and from the head, discouraging function (negative hydrostatics), hence, also, structures of the organs of special sense and of the face, teeth, and especially of the brain.

Passing mention may be made to the more important of devices to act as substitutes for Nature, such as artificial limbs (prosthesis), strictly surgical or orthopedic (orthokinetic) measures, and many devices which meet on the common ground of the internist and surgeon. Among these are various familiar supplemental devices, mechanisms, and agencies, *e.g.* artificial limbs now wonderfully perfected, also glasses to correct refraction errors and muscular anomalies of the eyes, protective colored glasses to modify light, etc.; artificial teeth, bridges, crowns, agencies to aid hearing, to supplement the body in numberless directions and particulars. We do well to recall the wonderful work of the surgeons at LaPanne in fitting papier maché supports to recent amputations whereby the sensitiveness of the nerves and muscles was preserved.

Great subjective benefit from arresting the venous circulation in the limbs in cases of heart disease is claimed by Engel (*Med. Klinik*, Berlin, October, 1912). By damming off so much of the venous blood the severest circulatory disturbances are mechanically combated; the arterial blood proceeds on its way unhindered, while the heart is relieved from much of the bulk of the venous blood. The passive distention of the right auricle grows less and the venous blood left in the trunk can be propelled much more easily into the lungs. The capillaries in the lungs thus receive less blood and are enabled to contract better while the lung capacity is increased, with consequent deeper inspiration of air, greater intake of oxygen and its better distribution to the coronary vessels, and hence to the heart muscle, with its consequent rejuvenation. The effect is also felt elsewhere, especially in the medulla oblongata and viscera. Once the vicious circle of the venous stasis is broken up in this way, the whole clinical picture may become transformed.

This method of temporary tying off venous blood from the limbs does not harm even when frequently applied—in direct contrast to digitalis—while the ease and simplicity of the technique commend it as a valuable acquisition to the physical means of treating disturbances in the circulation.

Retraining of Muscles which have been injured or where bones, tendons, or ligaments have been compromised.—This deeply significant topic is within the surgical domain but by no means outside that of the medical, for often an injured patient remains also under the care of a family adviser. He needs to become qualified to carry out certain details of treatment, hence should become familiar with the details and scope of the subject. The object is to maintain functionation, and to prevent contractures and adhesions in the movable structures, in particular of the tendon sheaths. The nutrition of the muscles also deserves consideration; likewise that of the motor centers. Joint structures, indeed, come in for first consideration; also periarthroidal, intraarthroidal, and associated parts. The needs for volitional control, encouragement, or restraint, vary with the nature of the lesion. Here counsel from the surgeon is constantly desirable.

The movements to be recommended are at first the primitives, gradually approaching the more complex. Some movements should be designed to equalize action where contractures are suspected or feared, or where overtension or tonic spasm coexists, in order to release spasm and to encourage action in weakened structures. Also the problem of recovering range, excursus, or ambit comes in later. First the impaired part must be held or adjusted in the best attitude for functioning to advantage.

It is convenient to indicate where, and by which muscles, movement shall be made, the direction, force, and the like. This is readily done by touching the part in which motion is to be made, directing it what to do, and how much effort can and should be made. Where spasm exists this can be released by a gentle tapping on the tense of rigid area or part and then by guiding the part which should move at a touch of the hand.

When the condition is one of irritation or inflammation the utmost nicety is called for. In suppurating joints the question becomes a delicate problem. The surgeon can best determine whether fluid needs to be removed. Where the condition is one of mere weakness, from whatsoever cause, the demand for skill, sympathy, and encouragement is large.

In paretic states, as Colin MacKenzie so strongly emphasizes, one must *never abandon hope*. The de-

sideratum is for the exercise of great care in finding a suitable position of advantage, a release from any or all positions of disadvantage.

When the slightest volitional movement can be evoked then the question is what proportion of the disability is psychogenic, due to discouragement, disappointments, hopes deferred, also there comes in the element of fatigue, exhausted energies, or peculiar exhaustibility of centers.

In order to awaken dormant energies in paresis stimulation can profitably be used by electricity, and also in order to demonstrate that the parts are vital enough to expect yet further action. Almost as good as electricity is the prick of a pin or needle to stimulate the skin. Deep pressure with a pencil point is especially useful over the sensitive spots or "nerve points," such as are pointed out in charts (*e.g.* one by Capt. Charles L. Ireland), used by electrotherapeutists to determine where responses can be elicited. Manipulations over these points can effect much in the way of release from inhibitions. Remember that the skin has areas or points in which pain only is felt, or only heat, or only cold, or only anesthesia persists. Since we have not yet fuller researches as to sensory fluctuations in these sensitive or insensitive points, the subject needs further study.

The most artistic muscle reeducation problem is in cases of paresis, especially of neglected pareses. Here the watchword is unbounded hopefulness, patience, persistence, and ingenuity. The index of recoverability lies in the degree of frank, cordial, consistent cooperation throughout the course, and afterward faithfulness in performance.

In addition to the fibrous, aponeurotic, and other adhesions or shortening of tendons, joint immobilities, there also exists often a deep-seated tenderness, soreness, or supersensitiveness to pressure or to movement, active or passive. This *sensory distress in paretics* has not been mentioned so far as my reading goes. It is a decidedly significant feature, one which probably contributes much to the total disability. To be sure, the distress is rather a discomfort than pain, has ceased to be noticeable, just enough to deter activities, but is *the great discourager of movement.* It is this subconscious distress which inhibits energetic action, rather than a loss of energy. Treatment includes diagnosis of local disabilities at every step, appraisement of real restrictions, of limitations, of differentiations between apathy, fear of being hurt, and habitual inertia.

Diagnosis and treatment is a continuous process from start to finish.

1504 Pine Street.

Pellagra in Paris.—A case of pellagra was shown before the *Société médicale des hôpitaux* recently. The disease picture comprised the deep erythema of the hands and feet, yellowish plaques on the neck suggesting a collar, intense and shining redness of the buccal mucosa, dysphagia, nervous excitation and bilateral paralysis of the sixth pair. A milk regimen cleared up these symptoms, although there remained some atrophy of the lower extremities and anesthesia of the legs. Certain violent pains yielded to gelsemium. The etiology of this case was paradoxical. The patient had not left Lyons for the past seven years and was prosperous. He had a "truck patch" of his own and ate meat. But he was fond of polenta and ate it several times weekly. No one else in the family developed the disease and apparently no one else had eaten polenta.—*La Presse Médicale.*

RECENT FRACTURES OF THE NOSE;

HOW TO DIAGNOSE AND TREAT THEM.

By WILLIAM WESLEY CARTER, A.M., M.D., F.A.C.S.,

NEW YORK.

It is unnecessary for me to urge the importance of this subject, for fractured noses are common in the experience of all. None of the socalled minor injuries that first come under the observation of the family doctor are entitled to more thoughtful consideration than that of a broken nose. Emphasis upon the primary importance of this injury is insisted upon, not on account of the immediate results, though these may sometimes be alarming, but because we now know from experience that when a nose is fractured, the various segments of the nasal arch may be separated or the broken fragments may rest at such an angle that not only will the nose be deformed but the respiratory function will be so disturbed that a chronic congestion of the nasopharyngeal mucous membrane soon develops with its train of symptoms referable to the nose, throat, and ear locally and the more general symptoms referable to nasal obstruction, such as mental hebetude and inability to concentrate the mind on a definite subject, headaches, and a general sluggishness of many of the bodily functions. If the victim of nasal obstruction has athletic aspirations, his accomplishments in this field are greatly curtailed by it. There is no reason why a fractured nose should not be treated with as much intelligent consideration as a fractured arm or leg, for it is just as important for the fractured parts to be placed in apposition and proper alignment before union occurs. No one will question the importance of the function of the nose, nor will anyone minimize the disadvantages to its possessor of a badly deformed nose.

When the nose is injured during childhood the developmental function of the septum is sometimes destroyed. I have reached the conclusion from my study of the dynamics of nasal development, that this function is chiefly to elevate the flattened bridge of the infant's nose, and that it is the chief factor concerned in giving prominence to the adult organ. Therefore if the septum is destroyed or its vitality impaired either by traumatism or disease, or if it is so thrown out of alignment by an injury that it is no longer capable of exerting pressure in a vertical direction, the nose will retain more or less of its infantile type, a saddle nose results, and for some reason, which does not appear altogether clear to me, there is a marked tendency to the development of atrophic rhinitis. Probably it is due to the interference with drainage from the ethmoid cells. The chief sequelæ of broken noses in adults are deformities varying in character and extent and nasal obstruction.

The diagnosis of a broken nose is not always easy, especially if several hours have elapsed since the injury, for on account of the obliteration of important landmarks by the swelling, the clotting of the extravasated blood, and the liability to confuse blood crepitus with bone crepitus, the situation is often obscure as to the exact extent of the injury.

In making the diagnosis, in all cases our chief reliance must be placed upon palpation. In infancy and early childhood the *x*-ray has no diagnostic value, as the tissues at this age offer so little resist-

ance to the rays. Even in adults, unless the fracture is very extensive or there is a displacement en masse of a large portion of the nose, the *x*-ray is of doubtful value, for fracture lines may be so easily confounded with suture lines and, unless stereoscopic views are secured, with the deeper structures of the nose. In radiographing injuries of the nose, the tube should be very soft and of low milliamperage. I have found that the positions giving the most accurate radiographic information are the exact profile and the frontonasal; in the latter the forehead rests on the plate and the tip of the nose is about one centimeter from the plate. Even in the best of plates, however, the shadow lines are so faint that their interpretation is attended by considerable uncertainty.

Fractures of the nose may involve the following structures: (1) the two nasal bones, (2) the septum, (3) nasal spine of the frontal, (4) nasal processes of the superior maxilla. With these the lacrymal bone may be involved in the fracture, but the injury to the lacrymal sac and duct is more frequently due to the traumatism and the overriding of the fractured segments of the nasal processes of the superior maxilla. The floor of the orbit, including, of course, the maxillary sinus, may be involved.

Fracture of the cribriform plate of the ethmoid may occur; this constitutes a complication which may involve serious consequences; its possibility should always be considered in severe fractures.

The fracture may be compound externally; it is probably always so intranasally. The sharp edges and points of the broken fragments may be seen or felt protruding through the mucous membrane into the nasal chambers.

Treatment.—Formerly the generally accepted treatment by both specialist and general practitioner was to introduce intranasal splints and stretch a piece of adhesive plaster across the bridge of the nose. In the light of our present knowledge such treatment does not deserve serious consideration and had best be dismissed with the statement that the patient would probably have been better off without treatment of any kind. Only recently I heard the statement from a man, whose judgment upon other matters is ordinarily good, that after adjusting the fragments with the Adams forceps, he puts on a piece of adhesive plaster to immobilize the parts and that he secures good results. The results of such treatment may be good enough temporarily to satisfy the doctor, the patient, and his friends, but this is before the swelling has subsided and long before the cicatricial contraction has occurred, which, after all, is the chief determining factor in deformity and obstruction cases following injuries to the nose.

The accepted time for the treatment of a fracture of the nose, from a scientific and practical surgical point of view, is either immediately after the injury or within the few days immediately following the complete subsidence of the swelling and any primary infection which may have occurred at the time of the injury. After this time the exudate has become more or less organized and we must contend with cicatricial tissue, and as a rule with an established deformity and obstruction as well. The treatment of these cases requires a different technique and special consideration and does not come within the scope of this paper.

Assuming that we have a fracture of the usual type, one involving the nasal bones, the nasal processes of the superior maxilla, and the septum: If the patient is an adult an *x*-ray examination may be of some value, but after all our chief reliance must be placed on palpation and inspection. Bone crepitus is usually elicited, but this may be confounded with blood crepitus. The nasal chambers should be packed with gauze or cotton soaked in a solution composed of adrenalin 1-1000 and cocaine 10 per cent., equal parts, before attempting to make a thorough examination. If bone fragments are found protruding through the mucous membrane, they should be pushed back into the tissues if possible; no bone or cartilage should be destroyed, every fragment is needed, for each constituted a part of the nasal arch, and if it is destroyed a certain amount of deformity is certain to result.

In my opinion, chemical antiseptics, such as alcohol, carbolic acid, etc., should not be used in the nose; they injure the mucous membrane and interfere with the normal nasal secretions, which are antiseptic in their action. Freshly sterilized physiological salt solution, freely used, will insure an aseptic field if anything will, and besides it will tend to preserve the vitality of the bone fragments and aid the recuperative powers of the tissues. I may state here that even an external compound fracture of the nose does not carry with it the same serious significance that a similar injury in some other part of the body does. There are several factors which favor the nose, the most important are: the abundant blood supply and the free anastomosis of the blood vessels; and the established local immunity to the flora that inhabit the nasal cavities. (Serious infected wounds of the nose are due to the introduction of alien infections.) Personally I attach much importance to the antiseptic value of the normal nasal secretion and to its mechanical action in flushing out the nasal cavities in all injuries of the nose, whether they be operative or accidental.

I know of no injury to the body where proper surgical aid, administered immediately after its infliction, yields more gratifying results, and the importance of prompt attention is greatly magnified by the future benefits to the patient, for the early adjustment of the several segments of the nasal arch not only restores the latter to its normal state, but it limits the formation of scar-tissue, the contraction of which is such an important factor in the development of deformity and obstruction to nasal respiration later on.

In these cases of recent fracture, the bridge-splint, an instrument which I devised several years ago, finds its most useful application. The action of this instrument is intended to duplicate the forces which Nature employs in the development of the flattened nose of the infant into the more prominent organ of the adult. Perhaps the numerous inquiries which I have received concerning this instrument offer a sufficient excuse for my again describing the technique of its application. The instrument consists of a bridge formed by two fenestrated wings which are hinged together in the middle. The distance to which these wings can be separated is regulated by a thumb-screw. The

second part of the instrument consists of two intranasal splints which are made at the time from plastic guttapercha, such as is used by dentists. Each of these splints is attached to a long silk suture which is threaded into a curved needle. The needle is passed from within the nasal cavity up through the dorsum of the nose, just below the ends of the nasal bones, and the splints are pulled into their position against the roof of the nasal cavities. The wings of the bridge are then thickly padded with gauze. This is absolutely necessary, otherwise necrosis of the skin will take place where these rest. The bridge is then placed in position over the nose. The sutures passing through the dorsum of the nose are now threaded through the fenestræ in the bridge which correspond to their points of exit from the nose. By means of the thumb-screw the wings of the bridge are adjusted so as to exert the proper pressure at the base of the nasal triangle. A sufficient traction is made on the sutures to pull the nasal bridge up into its normal position, and these are then tied together over the hinge of the bridge. If the lines of force exerted by this instrument are studied, it will be seen that the resultant of their conjoined action tends to construct a nasal arch of normal proportions by pulling the fractured and dislocated segments back into their former position. I usually leave the bridge on for about two weeks. It is self retaining, but if the patient is up and about, the weight of the bridge should be supported by means of a piece of adhesive plaster attached to the forehead.

The following precautions are absolutely essential: The nasal cavities must be cleansed daily with some mild alkaline solution or with physiological salt solution. Each day the sutures must be untied, the bridge removed, and the skin over the nose, and especially at the base where the bridge has rested, bathed with 95 per cent. alcohol. The bridge is then readjusted as before. In the use of this instrument great care must be exercised not to exert too much pressure. In proper cases, that is, where none of the component parts of the nasal arch have been destroyed, I have found this to be the ideal method for treating recent fractures of the nose.

In very severe injuries of the nose where fracture of the cribriform plate or base of the skull is suspected, treatment of any kind, especially forcible cleansing of the nose, is distinctly contraindicated. The rule should be "hands off" and complete rest until any possible avenues for the admission of infection to the brain box have been securely sealed. Meddlesome interference in cases of this kind is very apt to be attended by serious results. In these extensive injuries I believe that safety demands on the part of the rhinologist a delay of at least ten days before attempting to restore the shape and function of the nose.

If practically all of the bones of the face are involved in numerous comminuted fractures, the wall of the frontal sinuses and antra may be crushed in, as has happened in two of the cases coming under my observation. The displacement of the fragments is so great that satisfactory results can be secured only by an open operation. The fragments which cannot be made to remain in close contact by manipulation are drilled and sutured together with kangaroo tendon. If the external wound is insufficient to work through, an incision should be made from the inner canthus along the base of the nose and the tissues elevated over the fractured bones. In this area healing takes place so rapidly and readily that excellent results may be secured, even though the mutilation is extreme, if patience and perseverance are exercised by the operator; and if necessary incisions are made through the normal facial lines, disfiguring scars may be avoided.

In conclusion I may say that if, in recent fractures and dislocations of the nose, the same care is taken to place the parts in proper position and immobilize them as soon as possible after the injury, as is commonly done when similar injuries occur in other parts of the body, not only will many traumatic deformities and obstructed noses be avoided, but in young people the nose will continue to grow and develop normally.

THE ENDOCRINE ASPECT OF FEMALE STERILITY.

By ADOLPH JACOBY, M.D.,

NEW YORK.

INSTRUCTOR IN GYNECOLOGY, CHIEF OF GYNECOLOGICAL CLINIC, NEW YORK POSTGRADUATE MEDICAL SCHOOL AND HOSPITAL.

Not all cases of sterility are due to endocrine disturbance. There are numerous other causative factors which must be taken into consideration. Taking for granted that the male elements are present in sufficient number, actively motile, and normal in morphology, it is quite necessary to be certain that they pass on into the cervical canal maintaining their motility, and on into the uterine cavity. Certain considerations, such as depth of the vaginal pool and the acidity of the vaginal secretion, unless of inflammatory origin, are of minor, if of any, importance in this determination. So, too, is the position of the uterus, either in anteflexion or retroversion.

Excluding all instances in which inflammatory conditions are present, either of the cervix or of the tubes, or in which there is a sealing of the outer ends of the tubes as the result of plastic inflammation, or in which large ovarian cysts or uterine tumors are present, there still remains a large class of cases with apparently normal genitalia, or but slight deviation therefrom, who do not become pregnant.

In order to appreciate more fully and clearly the reason for this condition, and at the same time to afford a clue as to treatment, it will be advantageous to review the steps which lead up to pregnancy, and the subsequent fate of the ovum after fecundation takes place.

As a preparation for prospective pregnancy the ovary every 28 days discharges a mature ovum from a mature Graffian follicle. The follicle ruptures in the process and expels the ovum, together with the liquor folliculi, into the abdominal cavity. This process of rupture of the Graffian follicle cannot be considered as a mere hydrostatic process in which the accumulated fluid thins out the wall of the follicle, causing an atrophy due to occlusion of the blood supply, and when the ten-

sion becomes great enough, ruptures the wall at its weakest point, which, fortunately, happens to be at its free surface. If this were so, the follicle should enlarge along the path of least resistance toward the hilum of the ovary, and not rupture through the thick tunica albuginea. That the rupture does take place is due to the enzymotic action of the liquor, which digests the wall of the follicle and the tunica, and allows of the rupture and the escape of the ovum. The ovum, when cast out, is surrounded by the cells of the discus proligerus, known as the trophoblast.

After the ovum escapes into the abdominal cavity it is drawn up into the outer end of the tube by the current created by the ciliary motion of the epithelium lining the tube. It is usually here that impregnation takes place. When this happens menstruation is inhibited.

The follicle, after rupture, fills up with blood, which clots, and into which soon grow the lutein cells, forming the corpus luteum. If pregnancy occurs the corpus luteum persists and develops; if no pregnancy occurs it soon atrophies and forms a small scar in the ovary. While the corpus luteum is present no further ovulation takes place.

At these times certain changes become manifest in the uterus. The endometrial lining becomes thickened and the vessels engorged, and if no impregnation occurs, menstruation takes place, the endometrium shrinks to its normal proportions, and the ovum is lost. If pregnancy occurs, the endometrium, instead of returning to normal, increases in thickness, forming the decidua. Assuming that the impregnated ovum surrounded by its trophoblast cells is carried on out of the tube into the uterine cavity, and that it settles on the uterine wall, it does not stay very long in this situation, but at once, by virtue of the digestive action of the trophoblast layer, begins to eat out a small hole in the decidua, and embeds itself in the wall. These trophoblasts in their pentration puncture the minute capillaries and allow the blood to escape and bathe the growing ovum, thus furnishing it with nutrition for its continued growth until the formation of the placenta.

Now, what may occur in this physiological chain which will be responsible for the resultant sterility of the individual? In the first place, the follicle may not reach maturity, or else may not rupture and discharge its ovum, as a result of the failure of the enzymotic action of the liquor. In this case it may either regress or remain as a small follicle cyst. Secondly, if ovulation occurs normally, the passage of the ovum may be interfered with, either by a faulty ciliary action or by a maldevelopment or under-development of the Fallopian tube. Thirdly, if the impregnated ovum passes out of the Fallopian tube and reaches the uterine wall, it may fail to embed itself in the decidual lining, due to improper development of the uterus and endometrium, and be cast off. Or else it may endeavor to embed or actually do so, and by too active bleeding, caused by the capillary penetration of the trophoblast cells, it is washed out and lost. Or in other instances in which there is too great an engorgement of the endometrium and a resultant excessive menstrual flow, the impregnated ovum cannot firmly embed, and is swept away. Fourthly, in certain instances in which one pregnancy has taken place the corpus luteum, instead of undergoing atrophy, persists as a corpus luteum cyst, preventing subsequent ovulation and pregnancy.

The above enumeration at once gives us an idea as to what factors are at fault and how they may be remedied. It has been definitely established that the ovaries control the growth, development, and function of the internal organs of generation. Their removal or cessation of function is soon followed by the atrophy of these organs. The function of the ovaries is carried on by the follicular portion, including the corpora lutea, and by the interstitial portion. The functions of these portions are not similar. The follicular portion furnishes mature ova and, together with the corpora lutea, exerts a trophic effect on the endometrium, and more especially the corpus luteum, stimulates the development of the decidua, and at the same time exerts a protective influence against the too deep invasion of the trophoblast cells of the growing ovum. The corpus luteum, furthermore, aids in the inhibition of menstruation. The ovary as a whole exerts a trophic and developmental influence on the tubes, uterus, and vagina. Now, while it is true that the ovary is necessary and responsible for the perfect function and development of the genitalia, it is just as true that the other glands of internal secretion are responsible for the growth and development of the ovary. Notably in this connection are the pituitary, thyroid, and adrenals. The pituitary, in addition to its trophic action on the ovaries, particularly the follicular portion, has a stimulating action on the uterus, being responsible for its rhythmic contractions. The removal of the pituitary leads to atrophy of the ovaries. Disease of the pituitary is followed by ovarian dysfunction. Alterations in the secretion of the thyroid profoundly affect the ovary and its functions. Disease of the adrenals, especially the cortex, exerts a stimulating or inhibiting action on the ovary and its functions, dependent upon whether the adrenal hormone is in excess or deficient.

We may now proceed to interpret the previous pitfalls to pregnancy in the light of their basic disturbances. Thus the failure of the follicle to rupture can be ascribed to the failure of the pituitary to give trophic support to the ovary, especially the follicular portion. The faulty ciliary action or maldevelopment of the tubes, usually associated with a like condition of the uterus, is the result of a hypofunction of the ovary. The failure to embed is due to a hypofunction of the ovary, particularly the corpus luteum, which does not sufficiently exert its nutritive action on the endometrium and aid in the continued attachment of the ovum. In the excessive penetration of the trophoblast the corpus luteum is again at fault by its failure to exert its protective action against the too deep penetration of these cells. And, finally, the failure to embed, due to the excessive congestion of the endometrium causing an excessive menstrual flow, can be attributed either to an over-activity of the ovary, especially the interstitial portion,

causing a menorrhagia, or to a deficiency in the action of the corpus luteum in its inhibition of menstruation. It is, therefore, apparent that the chief factor in the production of sterility is a dysfunction of the ovary. A careful examination of the individual will usually reveal the gland or glands responsible for or participating in the ovarian deficiency, which, as previously indicated, are usually the pituitary, thyroid, and adrenals. The dysfunction of one or the other or several of these glands produces conditions which make it impossible to carry through the entire sequence of pregnancy from ovulation to embedding and growth of the ovum. That these conditions may be improved by the use of the proper gland extracts is certain. The following brief case reports are illustrative of some of the points brought out in the previous statements:

Case I.—R. S., age 29, married six years. Family history, negative. Past history, negative. Patient has been married for two years without becoming pregnant. Menstruatnon began at sixteen, has always been irregular, varying in interval from two to five weeks, of three days' duration, slight in amount, accompanied by slight cramps. Husband's spermatozoa normal. The patient is fairly well developed, slight tendency to stoutness, medium height, otherwise negative. Pelvic examination: Pelvic floor intact, vagina negative, cervix normal, uterus anteflexed, freely movable, normal in size, adnexa negative. This case is apparently one of insufficient ovarian function, as evidenced by the lateness in onset of menses, their irregularity, and scantiness. With this in view, ovarian extract, five grains, three times a day was given for two months. Pregnancy then took place and continued without interruption to full term. Breech delivery. Dead baby extracted.

Twelve months later patient was again delivered of twins. Subsequent to cessation of nursing the menses again became irregular, diminishing in quantity. The patient was having flushes, was extremely nervous and complained of cardiac palpitation. It is evident that the impetus to the function of the ovary by the administration of the extract and subsequent pregnancies is waning and that menopause symptoms are being manifested.

Case II.—R. C., age 28, married eight years. Family history, negative. Past history, negative. She has been married three years without becoming pregnant. Menstrual history, began at fourteen, has always been regular, two to three days in duration, scant flow, no pain, no clots. Husband's spermatozoa normal. The patient is somewhat stout, small in stature, otherwise negative.

Pelvic examination: Pelvic floor negative, vagina negative, uterus acutely anteflexed, slightly smaller than normal, movable; adnexa negative. Six months later dilatation and curettage and insertion of a glass stem was performed. Eight months after dilatation no pregnancy had as yet taken place. From the history and examination the case was evidently one of deficient development of the ovary plus a diminished activity of the pituitary. She was placed on five grains of ovarian extract three times a day, and in addition was given one-half mil, of pituitrin hypodermically three times a week. The subsequent menstrual periods showed a noticeable increase in the amount of blood lost. Three months after beginning treatment pregnancy occurred, which terminated uneventfully in delivery at term of a normal girl.

The foregoing cases are not cited as evidence that all cases of sterility can be made to become pregnant by the use of suitable organic extracts. But they should serve to call attention to a large class of cases which heretofore were either dilated or curetted or subjected to mutilating operations on the cervix, or else were merely put off in the hope that nature would ultimately effect the desired result. Every case of sterility where gross pathological conditions can be excluded warrants a careful study of the individual with a view to determining any malfunction of the endocrine system and the use of the indicated extracts for prolonged periods. In this way many a sterile female may become fecund, a result gratifying alike to patient and physician and a distinct asset to humanity.

THE ANTECEDENT FUNCTION OF THE TONSIL.

By J. A. HAGEMANN, M.D.,

PITTSBURGH, PA.

OTORHINOLARYNGOLOGIST TO THE PITTSBURGH HOSPITAL.

Embryology has established that each individual goes through a great many stages which his species has undergone during the course of its evolution. Ontogeny, the development of the individual, recapitulates phylogeny, the history of the evolution of the species. This doctrine, however, is not to be received without qualification; for, while evolutionary selection was steadily adopting improvements in organs and limbs, and adapting their several functions, a retrogressive tendency to eliminate useless and burdensome structures was simultaneously operating. Consequently there is here and there a hiatus in the register of descent. As embryonic development denotes rapid recapitulation, it signifies abbreviation and incompleteness of such recapitulation. Organs phylogenetically oldest, that, by virtue of their acquired resistance to vicissitudes became established in such individuals as proved themselves the hardiest during an incalculable period of time, have been found to persist in a rudimentary state even when no requirement for their endurance had arisen within an interminable period. Every animal organism requires that the gases contained in the tissues be continuously changed. The organs which perform this service in the lower forms of life are situated in the integument. As the scale to higher organisms is ascended, gills, specialized organs of respiration, appear. Gills in various stages of development are found in numerous aquatic forms of life. Simultaneously with other evolutionary changes incidental to the attainment of terrestrial habitation, the swimming-bladders, formed from an expansion of the primitive intestinal wall, and previously only employed by aquatic creatures to raise or lower themselves in the water, gradually assumed respiratory functions, developing more and more into a lung; while, as terrestrial life became unremitted by submersions, the gills lapsed recessively. However, over inestimably long periods of time, the turbulent waters would periodically engulf the neoteric terrestrial inhabitants, and such as had come to depend exclusively upon their primitive lungs for aeration would incontinently perish. By this method of natural selection the creatures that had inherited even fragmentary gills could survive, and the "habit" of retaining gills, regardless of imminent urgency,

in time became fixed. The circumstance that under the stress of inconstant tidal conditions, enduring for aeons, and during the very period in which the lowest forms of life were entering upon their long ascent that ended with man, made the under-water breathing organs inherent. Over so extended a series of geological epochs did these conditions prevail that the vestigial gills, when no longer required, eventually assumed a state of latency, not implying a loss of capacity to recrudesce pro re nata, but rather a condition of confirmed inactivity. The lungs of amphibians are very simple, and only when animals become enduring terrestrial inhabitants do they rely exclusively upon the lungs for oxidation of the circulating fluids.

Darwin says (The Origin of Species): "All physiologists admit that the swim-bladder is homologous, or ideally similar in position and structure with the lungs of the higher vertebrate animals; hence there is no reason to doubt that the swim-bladder has actually been converted into lungs or an organ used exclusively for respiration."

During the third week of the development of the human embryo four grooves are formed on each side of the neck. These denote the gill-slits of fishes. The arches at the front and sides of the neck in the human embryo signify the gill—including arches in fishes, and, just as in the fishes, the main blood vessel from the heart, the aorta, sends a ramification to each arch. As embryonic development progresses, the ear is formed in a portion of the first cleft. The lower jaw is formed in the first arch. Within the second and third arches the hyoid bone is developed. Within the fourth and fifth arches the thyroid and cricoid, as well as the tracheal and bronchial cartilages are formed. Identical skeletal parts are seen in the embryonic human throat and in the gill area of fishes. In certain fishes an operculum grows back from the second arch, covering the gills, thus forming a gill-niche. A similar proceeding takes place in the human embryo. A fold grows backward from the second arch, covering the third and fourth clefts, obliterating them. Not infrequently this effacement is imperfectly accomplished, and a small opening remains just above the inner end of the clavicle. This opening is the outlet of a fistula that is sometimes complete, communicating with the pharynx. Such a canal represents an unclosed gill chamber. When the branchial arches in the human embryo, representing the gill-breathing period of his pristine ancestry, disappear during the course of further development, the aortic branches within them are converted to other uses. Thus, those in the third pair of arches become in part the internal carotid arteries. While the branchiæ have disappeared in the higher vertebrates, their embryos show the slits on the side of the neck, proving, according to the axiom of ontogeny recapitulating phylogeny, that at an early stage of their evolution such animals were gill-breathers. It is probable that the tonsils are rudiments of pristine gills. At that early period the ear had not been evolved, and the waters swirled through the mouth and out of the then patulous branchial clefts, including those in which the ear afterward developed. The tonsils contain a number of crypts, into whose depths the investing mucous membrane ingresses, covering the parietes in every portion, thus presenting a considerably larger surface for the interchange of gases incident to subaqueous respiration. Corroboration of the plausibility of this theory may be deduced from contemplation of the anatomical relations surrounding and supplying the tonsils.

The palato-glossus muscles and the palato-pharyngei muscles with their mucous membrance investment, respectively, form the anterior and posterior pillars, between which the tonsils are located. It is no rash flight of fancy to idealize that the pillars at one period could be voluntarily contracted and relaxed, thereby alternately compressing and releasing the tonsils, incidentally expressing and sucking in the water. Further confirmation is found in the blood supply to the tonsils, presenting ample opportunity for aeration of blood coming from several directions. The dorsalis linguæ springs from the lingual artery, the ascending palatine and tonsillar from the facial, the ascending pharyngeal from the external carotid, and the descending palatine branch from the internal maxillary artery.

If the above outlined theory should prove tenable it would bring to an end the protracted speculation regarding the tonsils' possible special function. The tonsils serve no meritorious purpose, and whoever harbors hostile germs or bacilli in his tonsillar crypts may fitly exclaim with Hamlet:

"For though I am not splenitive and rash,
Yet have I something in me dangerous."

Highland Building.

Medicolegal Notes.

Evidence—Custom of Hospitals—Competency of Nurses as Experts.—In an action against a hospital for damages for the death of a patient, accidentally burned from an inhalator for vaporizing eucalyptus oil while under treatment for pneumonia, it was held error to admit evidence of the kind of inhalators used at two other institutions, for the purpose of showing negligence of the defendant. Testimony as to the general custom and practice of well appointed and managed hospitals in the matter of the use of inhalators would have been competent on the question of care and diligence exercised in the premises by the hospital. But such evidence must go to establish the general custom and practice in the business under investigation. The evidence in this case did not satisfy that rule. It was also held error to exclude evidence that the plaintiff tried to procure the defendant's resident physician to testify favorably as to the death being caused by the burns and not from pneumonia, since evidence of a party's falsehood or fraud in the preparation and presentation of his case is receivable against him.

The exclusion of evidence of graduate nurses with long and varied experience as expert witnesses as to whether in their opinion the patient would have died of disease at about the time she did die if not burned was held erroneous. One who is shown to be a graduate nurse, and to have been constantly engaged in the calling of a professional nurse for years, may, it is held, properly be called upon as an expert to give evidence of this character. Evidence of two undergraduate nurses was also held competent, the weight to be given to their testimony being for the jury.

For these errors in admission and rejection of evidence, judgment for the plaintiff was reversed.—Longuy v. La Société Francaise de Bienfaisance Mutuelle, (Cal.) 198 Pac. 1011.

THE DIFFERENTIAL DIAGNOSIS OF AFFECTIONS GIVING RISE TO CHRONIC JAUNDICE.

THERE are few problems more difficult to solve in practice than that of the nature and origin of chronic icterus. With the exception of cases in which the feces remain colored by the bile, it may be said that there is chronic jaundice from retention, but at the onset any diagnosis must be reserved, and it is only later in the course of the process that an hypothesis can be formulated. When the patient is seen at the onset, infectious or toxic icterus from some known or supposed cause will be suspected. When the initial phase has been passed certain morbid processes can be eliminated, still the field of hypotheses is yet vast in spite of a careful analysis of the case. Catarrhal icterus may tend to chronicity from the fact that a gastrointestinal catarrh—itself become chronic—may coexist and then the jaundice will persist, but it differs from the icterus of malignant disease by the variations in the intensity, remissions followed by renewed attacks, with parallel changes in the color of the stools. The liver and spleen may be very large, but a mere catarrhal jaundice lasting for more than five months has never been observed.

Calculous occlusion of the choledochus is often difficult to diagnose, and although in the majority of cases the migration of the calculus gives rise to a paroxysm of pain, in many cases this is absent, especially in elderly people. The intensity of the icterus, pruritus, and decrease in urea elimination are the same as in cancer. The liver is enlarged and in cases of biliary infection the spleen is likewise; digestion is disturbed and emaciation ensues. A good differential sign is a distended gall-bladder, which will occur in prolonged occlusion of the choledochus, likewise that of the intrahepatic and extrahepatic bile ducts; but in cancer of the hepatic duct the gall-bladder is not often distended. Another frequent, but not constant, sign is the variability of the icterus in calculous occlusion; it increases and diminishes, and staining of the feces does likewise. In malignant disease the jaundice does not vary. The liver in calculous occlusion has been known to atrophy; this is the biliary sclerosis described by Charcot and Gombault, which they produced experimentally by ligature of the choledochus. It may be added that Hayem maintained that in cancer there is hypopepsia, in hepatic lithiasis, hyperchlorhydria.

The cardinal symptoms of cancer of the head of the pancreas are a progressive continued icterus, emaciation and rapid cachexia, ascites, edema of the lower limbs, and gastric dilatation. In 80 per cent. of the cases the epigastric tumor cannot be perceived by palpation unless the case is seen at an advanced stage. Retention icterus accompanies dilatation of the gall-bladder; the liver is at first enlarged from retention of bile and then decreases from the progress of the biliary cirrhosis. Pancreatic steatorrhea may also be due to the absence of bile in the intestine; glycosuria is uncommon except, perhaps, at the onset of the pancreatic cancer. Cancer of the liver in its massive form can be readily diagnosed. There is no icterus here, but in nodular cancer, which, with massive cancer and adenoma, constitutes the third variety of primary hepatic malignant disease, chronic icterus is present in 66 per cent. of ahe cases, and when once it occurs it never decreases. Ascites, pain, anorexia, cachexia, and digestive changes make the diagnosis evident. In Hanot's disease there is chronic icterus but the feces remain colored. The spleen may be enlarged. This morbid process undergoes evolution in successive attacks, and death will occur at about four years from the onset. Cancer of the choledochus causes distention of the gall-bladder in seventeen out of eighteen cases (Devic and Gallavardin), and hypertrophy of the liver, while a neoplasm of the gall-bladder of the hepatic form does not give rise to icterus. The biliary form often causes icterus at an early date and this progresses in a continued way. Being a retention icterus, the stools are decolorized or this may result from occlusion of the choledochus by the tumor. When a malignant growth is seated at the junction of the choledochus, hepatic and cystic ducts, dilatation of the gall-bladder occurs in 50 per cent. of the cases. Cancer of Vater's ampulla gives rise to jaundice and clay-colored stools. The icterus may occur with complete remissions, but this is inconstant. It is therefore difficult to make a certain diagnosis, as there is no pathognomonic sign in any of these processes, and the varying diagnoses made by different observers abundantly prove this. The diagnosis will often be made only at autopsy, because even surgical interference is not always sufficient to enable us to come to a correct conclusion as to the condition of affairs.

THE DIAGNOSIS OF SEROSANGUINEOUS CYSTS OF THE SPLEEN.

IT can at present be assumed that the origin of sanguineous and serosanguineous cysts of the spleen is to be found in a peculiar condition of this viscus—anginomatous or varicose—which predisposes the organ to hemorrhage. The hemorrhage arises

either spontaneously or from a trauma. From the viewpoint of pathology a distinction should be made between encysted hematomata and serosanguineous cysts. The latter are true cystic productions having a wall covered with epithelium and the color of the liquid contents is of only secondary importance.

The symptomatology of serosanguineous cysts of the spleen is not marked, and usually these pathological products make themselves known by phenomena occurring in the viscera in proximity to the spleen, and at their onset at least they are very difficult to detect. When, however, a fluctuating tumor develops in the left hypochondrium, and especially if there is a history of previous traumatism in this region, a serosanguineous cyst of the spleen may very properly be suspected. The most delicate part of the diagnosis is to decide whether the morbid product is in the spleen or in an adjacent organ. At the onset of these cysts their existence is unsuspected, and as long as they are small they do not deform the spleen. But even later on, when the cyst has attained respectable proportions, pushing up the ribs and displacing the abdominal viscera, the diagnosis remains vague because, although it is easy to decide that a cyst occupies the left hypochondrium, it is less so to affirm that it is seated in the spleen. When the history of the case is not perfectly clear and the local signs are indistinct, mistakes are prone to occur, because it is more logical to think of common diseases rather than of infrequent pathological processes. Thus, an hydatid cyst of the left lobe of the liver may be mistaken for a cyst of the spleen, because percussion cannot always assign exact limits to the splenic dullness. This is also true of cysts of the tail of the pancreas and of the gastrosplenic omentum. Tumors of the mesentery can sometimes be made to move transversely, but in the case of the spleen the cyst, when it can be moved at all, can be displaced only in an upward direction. Cysts of the left kidney are of all the tumors in this region the ones which may most easily be confounded with splenic cysts, especially when these project into the lumbar region.

When the splenic cyst is very large and extends down to the pelvis it may be mistaken for a growth arising from some pelvic organ. But such an error can be avoided if the history of the case is carefully taken and it is ascertained whether the tumor developed from above downward or from the pelvis upward. If the splenic cyst has a thoracic development and if it gives rise to dyspnea, one is likely to jump at the diagnosis of diaphragmatic pleurisy, but hesitation will not be long if a careful exploration of the abdomen be made, as a cyst will extend much farther down than the most abundant pleural collection could ever do.

In any case of enlarged spleen malaria may be suspected, but a blood examination will settle all doubts as to the malarial nature of the splenic hypertrophy. In the case of a cyst, however, the diagnosis of the variety cannot be made clinically. The hydatid thrill is too infrequently obtained to be counted upon, and at present it is no longer regarded as pathognomonic, so that the diagnosis of this pathological process can never be completely eliminated in the cases under consideration. On the other hand, exploratory puncture offers too great risk and it will be of use only if the fluid withdrawn be submitted to careful laboratory examination. A blood cyst may lose its color, while on the other hand a serious cyst may become frankly hemorrhagic. The symptoms of anemia and internal hemorrhage should never be overlooked, as they may greatly help in the diagnosis for obvious reasons. A tumor rapidly developing in the left hypochondrium with signs of internal hemorrhage should always lead one to suspect a blood cyst or serosanguineous cyst of the spleen. In all cases the diagnosis of these pathological processes will be one of probability, and some known factor for causing changes in the spleen and a traumatism over the splenic area are the two fundamental facts that will indicate the probable diagnosis.

CARBON AND CHILDREN.

ONE of the most effective criticisms levelled against the psychoanalytic movement is its essentially simplistic nature. The new schools of spinal manipulation, say some, reduce everything to a subluxation of a vertebra, the psychoanalysts to an incest complex. On the face of it there is enough verity in this indictment to hurt, perhaps. But, to give the devil his due, let us examine the psychoanalytic doctrines a little more carefully. Tracing the individual's life far enough back we come to the new-born infant who, the psychoanalyst may assume, is autoerotic. As he develops in the family circle his personal contacts are limited largely to his parents. Now his reaction to either one of these may be love or hate. So we start out with four possibilities, two for each parent. That is, the child has four possible starting-points for his psychic development. He is later subjected to any number of influences, brothers and sisters, other relatives, servants, nurse-maids, playmates, and so on. Starting with any one of the four original possibilities, we have an endless number of variations. Any one familiar with the theory of permutations and combinations can easily see the vast variety of psychic reactions possible.

The psychoanalyst might seek an analogy in the field of organic chemistry. There we have carbon, with its quadrivalence, just as one child may be said to be quadrivalent. With the addition of hydrogen and oxygen in various quantities we have the practically limitless series of hydrocarbons. The quantity of these, as any student of organic chemistry knows, is sufficient to dazzle the mind, and how many million more of them are still undiscovered no one knows.

When carried back to its starting point, then, the psychoanalytic school comes to a rather simple statement: mother-love, mother-hate, father-love, father-hate. When we combine with any one of these possibilities the effects of parent surrogates of many sorts we soon have an endless field of

psychic possibilities. It is the psychoanalyst's task to take the psychoneurotic and endeavor to read the riddle of his distorted affective processes. He must try to trace the course of psychic development and discover the point of arrest or divergence from the normal. And this is no easy task.

MYTHOMANIA.

THE recently deceased French psychiatrist, Ernest Dupré, who died at the comparatively early age of 59, began his medical life as an internist, writing a monograph on biliary infections; thence he passed to neurology and ultimately to psychiatry (*Journ. de med. et de chir. prat.*, November 25, 1921, cviii., 22). For the past twenty years he had been identified with the latter, including its forensic aspect. The subject which greatly interested him and for which he is largely responsible in French psychiatry was the conception of the mythomaniac—of the habitual liar who relates tales of persecution and accuses others of crimes. He once held a series of conferences on forensic psychiatry in the Palais de Justice, going especially into criminal anthropology and sociology. Crime he presented from the viewpoint of etiology, symptoms, prophylaxis, and treatment. Certain psychoses naturally tend more to crime than others and present delicate forensic problems. Gross crimes are not in question here, but the more subtle ones in which self mutilation, instinctive perversions, hysteria, false accusation and pathological lying are concerned.

Mythomania as conceived by Dupré is a pathological tendency, more or less voluntary and conscious, toward lying and relating fabulous experiences. This tendency is practically normal in childhood as a natural consequence of the unfolding of the psyche, and gradually being attenuated becomes extinct about puberty. Hence, of course, the common refusal to allow children to testify. The statement that "fools and children tell the truth" is true only to a very limited extent. Beyond the child period mythomania is invariably seen in the disequilibrated and corresponds to a mental stigma of degeneration. This activity may be innocent but readily lends itself to crimes when the unbalanced and unstable individual has vicious tendencies. Ordinary mythomania in which the subject has more or less durable and systematized inventions passes into a higher degree known as delirium or imagination. Dupré also upheld the existence of a special emotional constitution.

LARGE DOSES OF ARSENIC IN TUBERCULOSIS.

SINCE the power of organic arsenic over an entire series of infectious diseases, chiefly of protozoan origin, has been shown, along with similar powers on the part of antimonials, attempts have been made to test these doses in various affections in which there is no actual indication. Sodium cacodylate in high dosage has been used in posthemiplegic lesions, Parkinson's disease, and other chronic nervous affections. The use of the same salt in chronic pulmonary affections in reality antedates that of salvarsan in syphilis, for Levrat in 1903 and Patry in 1912 essayed its use in tuberculosis, although in relatively small doses. Therasse in 1919 and Clouet in 1921 also reported on this subject. Further, in the last mentioned year Nidergang used this salt in colossal doses in the hope of influencing the bacillus favorably for the host. The drug was given by the intravenous route twice weekly—as much at a dose as 6 c.c. of a 50 per cent. solution without the least action on the microorganism, and consequently Nidergang condemned the idea. Clouet, writing in the *Gazette des Hôpitaux* for December 6-8, 1921, xciv, 96, does not agree with this condemnation. Irrespective of any action on the bacillus and without the necessity for such large doses, he claims good general reaction and gain in weight and strength. In other words, the drug acts by stimulating nutrition. The dose can be increased until the patient is taking one cubic centimeter of the solution daily, but the average dose over a long period is half the quantity. This is large by the book but not in comparison with the dosage of some authors. The remarkable roborant effect of large doses of strychnine in tuberculosis suggests that a combination of the two drugs in doses gradually increased should be even better than either alone.

COEXISTENCE OF CANCER AND TUBERCULOSIS IN THE SAME ORGAN.

BY one of those snap generalizations which are not peculiar to medical practice it was decided long ago that tuberculosis and cancer, being radically different from each other, could not possibly coexist in the same organism or at least in the same organ. It was admitted that epithelioma could and often did develop in the margin of a lupus, but this could be explained away by saying that cancer had a predilection to develop in any ulcer and that lupus was a very attenuated and slowly evolving form of tubercle. In some few cases cancer has developed in the tuberculous lung, breast, uterus, liver, etc., but this very rarity has been assumed to indicate some mystery of pathology. The grafting of a tuberculous process on cancer is even less frequent if possible and practically consists of tuberculous adenopathy regional to a primary cancer. Actual grafting of tubercle on cancer has been reported only two or three times. The great infrequency of these coincidences shows that the old generalization was not based on error of observation, but the fact remains that the two processes can coexist even in the same lesion. Duvergey and Jeanneney in the *Journal de Médecine de Bordeaux* for December 25, 1921, xcii, 19, append a bibliography of 16 recent references to the coexistence and mention two Bordeaux cases published before their own, which makes three from one locality within a short time. Villar found tuberculous axillary glands with a cancerous breast. Dubreuilh saw epithelioma on the back of the hand with tuberculous adenopathy and now the present authors relate the case of a superficial lesion of the scrotum, proved later to be cancerous, with a mixed cancerous and tuberculous inguinal adenopathy affecting a single lymph-node. It is assumed in such a case that originally there had been a tuberculous gland which was secondarily affected with metastatic cancer.

News of the Week.

Influenza and Pneumonia.—A bulletin issued by the New York State Health Department on Feb. 2 states that although New York City is experiencing an outbreak of pneumonia and influenza there appears to be as yet no unusual prevalence of these diseases up-State, according to the reports reaching the State Department of Health. The reports from New York City show a considerable recent increase both in cases reported as influenza and in cases and deaths from pneumonia. The State Health Department does not favor the use of vaccines for the prevention of pneumonia, in spite of the recommendation of the same by the New York City Health Commissioner. At the time of the last epidemic a thorough investigation of the efficacy of these vaccines was made, both by experiments upon animals, and by careful observation and analysis of the results of this method as used among 19,000 inmates of State institutions. This investigation, the report states, indicated that little or no protection against pneumonia was afforded by the use of the vaccines.

Veterans Ask Adequate Provision for Insane Comrades.—Disabled American Veterans of the World War recently presented a memorial to President Harding asserting that more than 3,500 mentally disabled former service men now in State institutions are victims of neglect, and urging the Government to take immediate action looking to the treatment of all such cases in Federal institutions.

Anglo-American Physiologists' Expedition.—Members of the Anglo-American physiologists' expedition to Peru to study the effect of Andean altitudes on the heart and other organs, returned on the Pacific liner *Ebro* on Feb. 1. They met at Lima, Peru, on Dec. 17 and went up the Cerro de Pasco mountains 14,200 feet above sea level. Later they made tests in the Carlo Francisco mountains, 17,000 feet high. The members of the party were under observation constantly and noted carefully the condition of the whites and natives living and working in the high places. Dr. Joseph Bancroft of Cambridge University, head of the expedition, said the results of the investigations would be compiled and used for commercial purposes. Many concerns have been put to much expense by the recall of men who cannot live at great heights after having traveled thousands of miles to their posts. Besides the benefit to business, Dr. Bancroft said, the tests and observations were of considerable value to medicine.

Rockefeller Institute to Establish Laboratory in Tropics.—Three representatives of the Rockefeller Institute, Dr. Carlos Chagas, Brazilian Commissioner of Health, and Dr. Fred F. Russell and Dr. Richard M. Pearce, sailed Feb. 3 for Brazil by the Munson liner *Aeolus* to establish at Sao Paulo a laboratory for the study of tropical diseases.

A Fund for Cancer Research and a Prize for a Cure of Cancer.—Following the announcement that Lord Atholstan of Montreal had offered a prize of $100,000 for the discovery of a cancer cure, he was urged to convert the fund to cancer research work. Instead of doing this Lord Atholstan has announced a donation of a second $100,000 for research.

Louvain to Study Cancer.—A Reuter dispatch from Brussels says that Louvain University has received a legacy of £20,000 to be used toward erecting a special building for cancer research.

High Cost of Medical Education.—President Lowell of Harvard University in his latest annual report raises a question of much interest to the medical profession and especially to medical students. He calls the rise in the expense of medical instruction "prodigious," and adds that it has reached a point where "we must ask ourselves how much can properly be spent on medical education and how much a community can afford to pay for it." In President Lowell's opinion the problem is so serious that he urges careful investigation, and suggests that there be inquiry whether, by improved methods, the equipments of the best medical schools cannot be applied to broader fields of educational service. He would have some plan devised whereby students now attending less highly developed schools might be enabled to benefit by the equipment of the schools that are provided with the best.

Statistics of Metropolitan Life Insurance Company for 1921.—A report of the Metropolitan Life Insurance Company just published announces that 1921 had the lowest death rate ever recorded among 14,000,000 industrial policy holders. The rate was 8.54 per thousand lives, which is lower by 13.7 per cent. than the 1920 death rate, and lower by 31.9 per cent. than the death rate of 1911. The death rate has been cut chiefly because fewer victims were being claimed by tuberculosis, pneumonia, influenza, Bright's disease and industrial accidents. The lower death rates for tuberculosis, organic heart disease and Bright's disease are regarded as evidence that the public health work of the last twenty years has been effective. One cause of death which resulted in greater ravages than ever was the automobile, the 1921 death rate from this cause being more than five times that of 1911. Deaths from alcoholism increased 50 per cent. in 1921 against 1920. The most conspicuous bad spot in the record of the year is the increased death rate for diphtheria. The mortality from this disease was higher than in any year since 1917. This is all the more deplorable because the means for the suppression of case incidence and case fatality should be known to every health officer and every physician in the United States and Canada. The scarlet fever rate was higher than for any year since 1914.

Hospital Notes.—Governor Miller to-day signed the McGinnies bill, which provides for the construction of a new State Hospital for the Insane at Creedmoor, L. I. When this hospital is completed the Kings Park State Hospital will be set aside entirely for World War veterans suffering from mental diseases. There are now 613 veterans being treated in State institutions in the metropolitan district. The bill carries an appropriation of $2,979,782. The hospital will be known as the Brooklyn State Hospital, Creedmoor Division, and will be under the management and control of the State Hospital Commission.

The new $150,000 hospital being erected by the International and Great Northern Railway Hospital Association at Palestine, Tex., is rapidly nearing completion.

The Sycamore (Ga.) Hospital was formally opened on Jan. 10. Dr. J. T. Moore and W. A. Harrison will have charge of the institution.

A hospital costing approximately $30,000 has been planned for Greenwood, S. C.

A modern tuberculosis hospital has recently been opened at Talihina, Okla.

The directors and officers of the National Jewish Hospital, located in Denver, held their annual meeting recently at the Hotel Biltmore, New York. Reports read showed that during its twenty-three years' existence the hospital has treated 4,000 patients, and that 60 per cent. of these were benefited. The financial report showed a deficit of $25,000.

Buffalo Doctors Assail Free Dispensaries.—The Physicians' Protective Association of Buffalo, at a meeting held Jan. 30, adopted resolutions attacking health centers and free dispensaries. The resolution states that there is danger of "pauperization in the form of medical aid," and a condition is developing "that will make it impossible for young physicians to earn a livelihood in the practice of medicine. We have escaped some of the dangers of State medicine and its direful effects," the resolution states; "but influences still exist that are prone to make the practice of medicine a socialized industry, instead of a profession." It is alleged that wealthy persons are treated free of charge by institutions maintained by the city.

To Study Sanitary and Health Conditions in Europe.—Colonel E. C. Gibbs sailed on February 4 for Europe to make a study of typhus, cholera, and other diseases in Poland and Russia for the information of the Health Department and physicians of this city, that intelligent precautions might be taken against any epidemic now raging in Europe.

Mme. Curie an Academician.—The Academy of Medicine of Paris has elected Mme. Curie to fill a vacancy in its membership. This is the first time a woman has ever received that honor.

Women Uphold Vivisection.—The New York City Federation of Women's Clubs, at its fifty-seventh convention at the Hotel Astor on Feb. 2, defeated by an overwhelming vote a resolution that dogs be exempted from scientific experimentation.

Dr. D. W. Scanlan has been elected chief of staff of the Atlantic City Hospital to succeed Dr. C. H. Canning, who has resigned because of ill health.

Dr. Raymond F. Kircher of Albany has been appointed district physician, to fill the vacancy caused by the death of Dr. Eddy S. Haswell.

Dr. Smith Ely Jelliffe has been elected president of the New York Psychiatric Society.

The Medical Section of the American Life Convention will hold its twelfth annual meeting at French Lick Springs, Ind., March 1, 2 and 3, 1922, under the chairmanship of Dr. C. H. English of Fort Wayne, Ind.

The Pennsylvania, New Jersey, and Delaware Branch of the American College of Surgeons will hold its annual convention in Allentown, Pa., on March 27 and 28, 1922. Dr. Charles D. Schaeffer of Allentown is chairman of the committee of arrangements.

Positions Open to Physicians.—The Civil Service Commission of the State of New York announces the following unwritten examinations to be held Feb. 25, 1922: *Assistant Physician and Assistant Surgeon,* State and County Institutions, at varying salaries. Immedate appointments are expected at Letchworth Village at from $1,800 to $2,200 per year and maintenance. *Medical Assistant to Director,* Grasslands Hospital, Westchester County, at a salary of $2,000 and maintenance. Applicants must be duly licensed practitioners of medicine in this State or in some other State. Application forms and further information may be obtained by writing to the Civil Service Commission, Albany, N. Y.

Vacancies for Public Health Nurses.—The United States Civil Service Commission will hold an open competitive examination for the position of consulting public health nurse and to fill vacancies requiring similar qualifications, at salaries of $1,200 to $2,800 per year, and the increase of $20 a month granted by Congress. Further information may be obtained by writing for Form 2118, stating the title of the examination required, to the Civil Service Commission at Washington, D. C., or to the post office or custom house in any large city.

Charitable Bequests.—Under the will of Julius Kayser bequests of $10,000 each are made to the Hebrew Orphan Asylum, Mt. Sinai Hospital, United Hebrew Charities and Montefiore Home, New York.

The New York Ophthalmic Hospital, Flower Hospital, New York, and the Greenwich (Conn.) Hospital will each receive a bequest of $150,000 under the will of Commodore E. C. Benedict of Greenwich.

By the will of the late Mary C. Ihling of Philadelphia the sum of $1,000 is bequeathed to the Home of the Merciful Saviour for Crippled Children, and the sum of $1,250 for the North American Sanitarium for Children at Atlantic City.

Medical Society Elections. — THE SPOKANE COUNTY MEDICAL ASSOCIATION, at its annual meeting held in Spokane, Wash., Jan. 12, 1922, elected the following officers for the ensuing year: *President,* Dr. Carl Weisman; *Vice-President,* Dr. Charles Doland; *Secretary,* Dr. Arthur Betts; *Treasurer,* Dr. Mitchell Langworthy.

THE LEHIGH COUNTY MEDICAL SOCIETY, at its annual meeting held in Allentown, Pa., Jan. 10, 1922, elected the following officers for the ensuing year: *President,* Dr. I. J. Weida; *Vice-Presidents,* Drs. John D. Matz and M. S. Kleckner; *Secretary,* Dr. J. Treichler Butz; *Treasurer,* Dr. W. D. Kline.

THE PIKE COUNTY MEDICAL SOCIETY, at its annual meeting held in Williamson, Ga., Jan. 14, 1922, elected the following officers for the ensuing year: *President,* Dr. J. C. Beauchamp; *Vice-President,* Dr. I. B. Howard; *Secretary and Treasurer,* Dr. M. M. Head.

THE PHILADELPHIA COUNTY MEDICAL SOCIETY, at a stated business meeting held Jan. 18, 1922, elected the following officers for the ensuing year: *President,* Dr. J. Norman Henry; *First Vice-President,* Dr. Ross Hall Skillern; *Secretary,* Dr. William S. Wray.

THE ASSOCIATED PHYSICIANS OF LONG ISLAND (N. Y.), at their twenty-fourth annual meeting held in Brooklyn, Jan. 28, 1922, elected the following officers for the ensuing year: *President,* Dr. Joshua M. Van Cott; *First Vice-President,* Dr. Hugh Halsey; *Second Vice-President,* Dr. Arthur Jacques; *Third Vice-President,* Dr. L. Howard Moss; *Secretary,* Dr. James Cole Hancock; *Treasurer,* Dr. Edward H. Morse.

The Lutheran Hospital Association of Fort Wayne, Ind., at a meeting held on Jan. 21, 1922, elected the following officers: *President,* Dr. H. A. Duemling; *Vice-President,* Dr. W. O. Gross; *Secretary,* Dr. E. H. Schlagel; *Treasurer,* Dr. E. E. Morgan.

Obituary Notes.—Dr. Frank Bates Livermore of Barberton, Ohio, died from cerebral hemorrhage at Youngstown, Ohio, on Jan. 17, at the age of forty-nine years. He was graduated from Cleveland University of Medicine and Surgery in 1895.

Dr. Howell White of Fishkill, N. Y., died suddenly of heart disease at his home on January 23, at the age of sixty-five years. He was graduated from Bellevue Hospital Medical College in 1879.

Dr. Alexander Strong of New York, a graduate of the College of Physicians and Surgeons, N. Y., in 1871, died of heart disease at his home on January 22, at the age of seventy-five years.

Dr. Louis H. Landman of Cincinnati, who retired about a year ago and went to Palestine to practise his profession free among the Jews, died there on January 25, at the age of sixty-three years. He was graduated from Miami Medical College, Cincinnati, in 1895.

Dr. Ella B. Everitt, professor of gynecology at the Woman's Medical College, Philadelphia, from which she was graduated in 1891, was killed on January 24 when her automobile collided with a motor truck. She was gynecologist to the Woman's Hospital and to the Philadelphia General Hospital. She was a member of the Obstetrical Society of Philadelphia, the Medical Society of the State of Pennsylvania, the Philadelphia County Medical Society, and the American Medical Association.

Dr. Paul F. von Scheliha died at Philadelphia on January 18. He was graduated from Hahnemann Hospital and Medical College of Pennsylvania in the class of 1889.

Dr. James Francis Sullivan of New York, a graduate of New York University Medical College in 1878, died suddenly of heart disease on Feb. 4, at the age of sixty years.

Dr. Charles Thatcher Hubbard, a graduate of Harvard Medical School in 1861, and a Civil War veteran, died at his home in Taunton, Mass., on Jan. 16, at the age of eighty-one years.

Dr. Robert Hazlett Bullard of Tridelphia, W. Va., a graduate of the Medical College of Ohio, Cincinnati, in 1877, died on Jan. 11, at Oakmont, W. Va., at the age of seventy years.

Service Bureau.

Regular subscribers to the Medical Record who desire information on any professional matter are invited to send their inquiries to the office of publication. Replies will be sent by mail as promptly as possible. Questions and answers of general interest may be published from time to time. When abstracts of articles from other journals are furnished the cost of typewriting will be charged.

Purchases will be made of articles of any description wanted by subscribers; a check sufficient to cover the cost should be sent with the order.

Subscribers visiting New York are welcome to use the office, 51 Fifth Avenue, as a temporary address for receiving and forwarding mail, telegrams, or small packages.

Correspondence.

THE HOMER PIGEON IN RURAL PRACTICE.

To the Editor of the Medical Record:

Sir:—Some twenty years ago I wrote an article for your journal on "Homing Pigeons as Medical Messengers or Bulletin Bearers." I have used them in my practice and for pleasure ever since then, and find them fully reliable within their limitations. When the telephone first became common in rural districts I thought the pigeon service hardly worth while, but they render services that the phone system cannot. Many a message of too private a nature to trust to gossipy rural telephone lines has been freely entrusted to these discreet servants. Once I lost the key to my cowhide medicine case and was quite annoyed for a few hours till one of the birds I had left on my morning round returned with the little key attached to his leg.

The World War revived popular interest in these birds to such an extent that there are thousands of users of them in the United States where there were dozens twenty years ago. The Government has done much to encourage their use. Birds which took an active part at the front in France as dispatch bearers have since been the parents of valued racers and workers in this country. Breeding and training them makes a pleasing hobby and it is fascinating to watch the results of crossing different strains, for pedigrees are kept and registered as accurately as those of blooded cattle or horses. Many good looking birds without ancestors trained for flying are worthless for this purpose.

Chas. L. Lang, M.D.

Cato, N. Y.

OUR LONDON LETTER.

(From Our Own Correspondent.)

London, January 20, 1922.

The Question of Venereal Disease.—There is still no agreement between authorities here as to the best means for coping with venereal diseases. Those who believe in preventive measures support the policy of the Society for the Prevention of Venereal Diseases, the members of which advocate immediate self-disinfection, while those who regard this measure as hard, if not impossible of successful execution and opposed to principles of morality, are in accord with the views of the National Council for Combating Venereal Diseases, which provide for early treatment and for early disinfection to some extent. It seems a pity that these two bodies cannot reach an agreement by compromise. Lord Dawson, the well-known London physician, is of the opinion that steps in this direction ought to be taken. He has written more than one letter to the *Times* for the purpose of advancing this opinion. He proposed that the differences of views would be more easily settled if a conference between the National Council for Combating Venereal Diseases and the Society for the Prevention of Venereal Diseases were held and the following propositions were considered (1) What in the present state of knowledge are the most efficient medical measures for preventing these diseases. (2) How far is it ethically justifiable to apply such measures. Let those, he said,

who have the technical knowledge get together in conference and try to arrive at conclusions on the medical and administrative aspects of the problem, uninfluenced by any ethical prepossessions. Then with such conclusions before them, the medical profession generally and the public must decide whether it is ethically justifiable to found a policy upon them. Such a conference might gain the support of the Ministry of Health. A few days later Lord Dawson wrote again to remove some misconceptions his previous letter appeared to have aroused. He explained in this letter that something wider than a mere joint meeting of the two opposing societies was needed. These societies were too deeply committed on both the medical and ethical aspects of the problem to constitute alone the best tribunal of inquiry. The political method of give and take was not suited to scientific investigation. His hope was that some impartial body possessing the confidence alike of the public and profession would gather together a body of experts, representative not only of the societies, but of skilled medical opinion outside the conflict, to investigate thoroughly and without prejudice what are the best medical measures for preventing the disease. A conference took place on October 22 between the Standing Joint Committee on Venereal Disease of the Medical Women's Federation and a deputation from the Society for the Prevention of Venereal Diseases. However, as the Council of the Medical Women's Federation made it a condition of the meeting that no report of the conference should be published without the written consent of those present, and as the Medical Women's Federation flatly refused to give this consent, nothing has been made public with regard to the proceedings on the opinions expressed, again at a conference of Medical Officers of Health, Venereal Diseases Officers, and other specialists in the treatment of venereal diseases, to be held in Edinburgh on January 24, although the entire matter is to be fully dealt with, the proceedings will be conducted in private and those who accept the invitation to be present, or who take part in the discussion, will be understood to consider any opinions they may themselves express or that may be expressed by others as confidential. It seems that a conference on the lines suggested by Lord Dawson might serve a good purpose by ventilating opposing views and thus might clear away some of the misconceptions which now exist. True, a discussion of the question might not bring about any tangible result. On the other hand, it might aid in smoothing away some of the difficulties in the way of an understanding, and as said before a compromise might be reached.

Obituary.—I mentioned in my last letter that I hoped to be able to give some further and more intimate details of the late Sir German Sims Woodhead, for many years Professor of Pathology in the University of Cambridge. Dr. W. E. Carnegie Dickson, who was assistant of Professor Greenfield, the great Professor of Pathology in Edinburgh, and who married Miss Greenfield, has been good enough to obtain for me a few personal reminiscences of Woodhead. But before quoting these it will be in place to give a more full account than given in the previous letter, of the Cambridge professor's career. Woodhead was by birth a Yorkshireman, the eldest son of the late Joseph Woodhead, editor and proprietor of the *Huddersfield Examiner*. He was a medical student of Edinburgh University, took there the degree of M.D. in 1881, obtaining for his thesis the gold medal. He also studied in Berlin and Vienna and in 1882 became F. R. C. P. Edin. On his return to Edinburgh he was appointed Demonstrator of Pathology at the university and came into somewhat close touch with the well-known Dr. Rutherford, Professor of Physiology. Before receiving the appointment of Professor of Pathology in Cambridge University he held several important posts. He came to Cambridge in 1899. He was unfortunate in this respect that in all his appointments he had first to fit up and organize the laboratories, of which he was in charge. Of course this occupied a great deal of time which might have been more profitably expended in research work and in his legitimate work. He was an earnest and enthusiastic worker and an especially kindly and careful teacher. At the outbreak of the war, although he was then in failing health, he immediately placed his services at the disposal of the War Office. He served during the war in various localities, did valuable work, and in 1917 was made Inspector of Laboratories in Military Hospitals in the United Kingdom. His war duties tried him severely, especially those of inspector of laboratories involving as they did long and frequent journeys by rail and motor. For his military services he was made K. B. E. in 1919. Woodhead was appointed senior assistant and demonstrator to Professor Greenfield in 1881, a position he held for six years. In an appreciation of Greenfield, written by Woodhead, he said that during the period he was with him he came without abating one jot of his admiration for Hamilton, to appreciate the sterling qualities that had gained for Greenfield the good opinion of Burdon-Sanderson, Paget, Lister, and men of similar standing and withal the appointment to the chair. There is no doubt that Woodhead's connection with Greenfield was of immense advantage to him and probably his six years with him paved the way to his subsequent appointment at Cambridge. Woodhead was a staunch, indeed an ardent advocate of temperance, but he also possessed the saving grace of a keen sense of humor. One of the little episodes that used to delight and entertain his brother pathologists at the dinners of the Pathological Society of Great Britain was when they prevailed on Woodhead to sing "At the Tavern Door." He would rise with a self-depreciatory air, push his fingers through his hair, in order to give himself a most disreputable appearance and then proceed with the song. It explained fully the effects and delights of alcohol, and how the observer from the said tavern door was able to observe two moons and other curious phenomena and how after such observations he turned back to the tavern just for "another." This showed the kindly and tolerant nature of the man. But kindliness and tolerance were essential characteristics of the man who, deeply religious himself, viewed with infinite sympathy and under-

standing the failings of his brother. Indeed, he was one of the most lovable and truest of men, who deemed no trouble too great to aid anyone who was in need of assistance or encouragement. It may be of interest to state that only ten days before his death he was at Dr. Carnegie Dickson's house in London to discuss the details of the Greenfield Memorial Prize. Woodhead's name will go down to posterity as a first-class pathologist, but what is even better as a good man, a true lover of his kind. He was particularly fond of children.

LETTER FROM SWITZERLAND.

(From Our Own Correspondent.)

GENEVA, Feb. 1, 1922.

The Third Congress of the History of Medicine will meet this year in London from July 17 to 22. The subjects to be discussed are: (1) The epidemic and endemic foci in medieval times, and (2) the history of anatomy. After the number of papers to be presented on these topics is known, a certain number of seances will be allotted to members contributing memoirs on various subjects. At the present writing a full attendance may be confidently expected. The program will unquestionably be very attractive, and London is apt to be at its best in July.

Fatal Result of a Students' Duel.—A German student, Karl Walter, of the University of Jena, has been sentenced by the court of Rudolstadt in Thuringia to six months imprisonment in a fortress for killing, in a duel, a fellow student named Wissens. The two belonged to rival students' associations, and fought in the traditional manner with light swords, body paddings, gauntlets, spectacles, and all the other paraphernalia that had come down from their equally unenlightened ancestors. In the course of the duel, Walter got home with his sword on Wissens with such effect that the latter's skull was cut through. Septic poisoning and cerebral inflammation followed—the principles of Lister are always treated with fine scorn on these occasions—with the result that Wissens died in hospital after an operation. Duelling was technically forbidden by law, even under the monarchy, but was lightly treated because it was thought to foster the military spirit. That these things have not materially changed under the republic is shown by the proceedings at Rudolstadt. The court found Walter technically guilty, but in consideration of "the fact that his adversary must have had a very thin skull," it inflicted the usual nominal sentence.

Osteomalacia in Children.—Some recent work on osteomalacia in children, which has not as yet found its way into the medical press, has been carried out by Dr. M. Molcho of Bazarkdjik, Bulgaria. He concludes that this disease must no longer be considered as an affection special to adult age, but should also have a place in infantile pathology. Osteomalacia arising in children over five years of age can readily be differentiated clinically from rickets, but during early life the two morbid processes are much harder to diagnose. The disease does not appear to have any particular predilection for either sex, girls being as frequently afflicted as boys. The pathogenesis remains to be elucidated, but in accord with Hutinel, Molcho believes that of all the hypotheses so far put forward, that of the secretions of the endocrine glands—thyroid, hypophysis, and suprarenals—is probably nearer the truth. From the viewpoint of diagnosis, infantile osteomalacia offers characteristic clinical symptoms and radiographic and pathological data. The evolution of the affection is relatively slow, especially when an early diagnosis has been made and adequate treatment instituted early in the evolution of the process. But the prognosis is bad, as these subjects, being in a condition of lessened resistance, usually die from some intercurrent affection. The treatment is both surgical and medical, but the former should be abstained from whenever possible. Proper feeding, good hygiene, tonics, and especially the exhibition of the extracts of thyroid, hypophysis, and suprarenals appears to be the best practice, at least for the present.

Typhoid Fever in Vaccinated Subjects.—A good deal of attention has been given of late to the question of typhoid fever occurring in vaccinated subjects, and I think the present status of this subject, as viewed by the continental profession, may be summarized briefly as follows: If the term typhoid fever be taken in its purely clinical sense, hence comprising the paratyphoids as well, the disease is frequently encountered during epidemics in subjects previously vaccinated, no matter what vaccine has been employed. A distinction must be made between typhoid fever occurring in subjects who have been vaccinated for a proper length of time with a sufficient dose of dead bacilli and that developing shortly after a hasty vaccination. In the first case, when the typhoid appears in previously vaccinated subjects, it follows a mild evolution and is frequently accompanied by relapses—in which case the process may in reality be a paratyphoid. The value of vaccination is proved by the absence of serious cases and by no fatalities.

In the second category of cases—the typhoid developing soon after an emergency vaccination—the clinical aspect of the disease closely resembles that in a non-vaccinated subject. Nevertheless, the gravity as a rule is much less the longer the time ensuing between the febrile onset and the injection of dead bacilli. In other words, the injection appears to weaken the defensive properties of the organism when it is given at the time when dissemination of living virulent germs has actually occurred. But when it is given before the living bacteria have had time to undermine the economy, it fortifies the defensive action of the organism. In 1915, Menville (Thesis, Paris) distinguished typhoid fever developing after a single injection of 500,000,000 bacilli and that following two injections, the first of 500,000,000, the second of 1,000,000,000. Typhoid fever in the first category is the more frequent and its evolution does not appear to be influenced in any way by the vaccination, for serious cases are not uncommon. Absence of reaction after the injection is the rule. In many instances where the patient is vaccinated a week or ten days before the advent of pyrexia the disease has a mild evolution.

There are two different types of onset. In the first a phase of perfect health separates the injection from the onset, in the second this phase is marked by a series of malaises. The existence of this clinically confirmed period of incubation in subjects who do not become actually ill until more than two weeks after vaccination should lead one to suspect that the injection was given to individuals already carriers of the bacilli. After the lapse of four weeks following vaccination typhoid becomes less frequent, but assumes a medium intensity, the patient reacting as if he had not been vaccinated. After two successive injections the results are similar, and it is to be noted that a second injection made in the incubation period of typhoid fever aggravates the prognosis of the disease. The prognosis is invariably better if the second injection precedes the onset of the typhoid by one to three weeks. The majority of cases develop about a fortnight after the vaccination and during this time many complain of feeling ill, probably because they are latent carriers of living virulent bacilli. Hence in practice it is not well to give massive doses of vaccine during epidemics as a prophylactic, repeated and progressively increasing doses being far better. Subjects who have been methodically vaccinated some time previously are not completely protected against the disease, but in them it will be mild. Subjects vaccinated during an epidemic with massive doses will probably have an attenuated form of the disease unless vaccination is done at the onset of the typhoid.

1. The Treatment of Carcinoma of the Prostate.—John H. Cunningham states that the difficulty in dealing successfully with carcinoma of the prostate surgically is dependent chiefly upon the fact of the relatively slow development of the local focus and the relatively rapid dissemination of metastases. From the diagnostic standpoint there are certain subjective symptoms and objective findings which, in many instances, differentiate carcinoma of the prostate from benign hypertrophy. Early metastases in the pelvic nodes, resulting in sciatic nerve pressure and giving the usual symptoms of sciatica, are common, and not infrequently the most pronounced symptoms of which the patient complains. With such pain radiating to one or both sciatic regions, there is often an associated sacral and groin pain, all of which subjective symptoms should excite suspicion of malignant disease of the prostate with pelvic metastases. If during the preoperative examination a condition in the gland is discovered which excites suspicion of carcinoma, a complete *x*-ray examination of the whole skeleton should be made, as bone metastases, both osteoplastic and osteoclastic, are not uncommon. It is today generally admitted that radical operation as a curative means is futile. All that can be accomplished is to relieve the local condition either by operation, combined with radium therapy in certain instances, or by radium therapy alone. In a large group of patients including those with few distressing symptoms of prostatic obstruction and those with recurrence of the disease locally, following operation, Cunningham has adopted a combination of the methods of radium therapy employed by Barringer and by Young. He supplements the treatment as employed by Barringer by the method employed by Young about three weeks after the needling. The treatments consist in making daily applications of radium for 100 millicurie hours by means of a special instrument introduced into the prostatic region through the rectum, urethra and transvesically. The results of this treatment have proven conclusively to the writer's mind that radium employed by the Barringer or Young method has a strikingly beneficial result.

2. Some Figures on Cesarean Section.—John M. Birnie refers to an article in the *Journal of the American Medical Association* for Febraury 24, 1917, in which a writer on cesarean section gives the mortality as over 50 per cent. in several good-sized cities near Boston, and says that no doubt similar figures obtain in other parts of the country. He felt that the mortality in Springfield was not "surprisingly high" and has endeavored to ascertain what the actual figures were in his community and what the pregnant woman might expect from the procedure in the hands of local operators. In 12½ years 217 cesarean sections were performed in five hospitals in Springfield. Two of these were performed by surgeons from a distance and are excluded from the series, leaving 215 cases. The maternal mortality in the series was 11 per cent., which compares favorably with Davis's figures from the New York Lying-in Hospital, namely, 10.7 per cent. in a series of 571 cases. The fetal mortality in the Springfield series was 20.5 per cent. In the series there were 53 cases of severe toxemia with a maternal mortality of 24.5 per cent. and a fetal mortality of 21.8 per cent. If these could be excluded from the series the maternal mortality would be 6.1 per cent. De Lee gives the maternal mortality in eclampsia as from 20 to 45 per cent., and the fetal from 30 to 60 per cent. These figures, the writer asserts, show not a "surprisingly high mortality," but an astonishingly low one.

3. Jejunostomy.—Irving J. Walker makes a plea for the early use of jejunostomy as a surgical measure. In conditions such as carcinoma of the esophagus; ulcer of the cardiac end of the stomach where removal is impossible; obstruction of the pyloric end of the stomach, due to cancer or ulcer; bleeding ulcer of the stomach or duodenum; in certain cases of nausea and vomiting of pregnancy; in persistent vomiting with localized peritonitis, and in certain forms of intestinal obstruction, jejunostomy constitutes a procedure by which intestinal gas and toxic material may be well cared for and through which nutrition, drugs, and fluids can be introduced, and which, if utilized in time, is a life-saving measure.

1. The Therapeutic Effect of Venesection, with Particular Reference to Lobar Pneumonia.—W. F. Petersen and S. A. Levinson call attention to certain alterations in the blood brought about by venesection which may account for the therapeutic effects not infrequently noted by capable clinicians of the older school as well as by more recent observers. Among these changes are the well-known alteration in the coagulation balance and the reactive polymorphonuclear leucocytosis, the increase in nitrogen excretion, increased nonprotein nitrogen content of the blood, alteration in the lipoid balance, hyperglycemia and diminution in the alkali reserve after bleeding. Attention has also been called to the splanchnic stimulation which occurs after hemorrhage. As evidence of the physical alterations in the serum it had recently been shown that the Kottmann reaction becomes positive after bleeding, that the serum antiferment is in most instances diminished, and that the sedimentation time of the red blood corpuscles in the plasma is altered. The alterations above enumerated indicate that we must consider bleeding as a form of protein therapy. As to which of them may be considered the primary cause in this form of protein therapy is, of course, undetermined. The writers call particular attention to another factor which seems to them to be of importance in the explanation of the therapeutic effect of venesection in lobar pneumonia, namely, the ferment-antiferment balance that exists in the pneumonic exudate of the consolidated lung between the amount of enzyme present (protease and ereptase from disintegrating polymorphonuclear leucocytes) and the antiferment of the plasma and tissue exudate. Venesection may have a direct influence on this balance. The depletion of the fluids in the vascular bed results in a prompt compensation in fluids drawn from the tissue spaces. The direction of the current would be from the exudate to the circulation. The amount of antienzyme would therefore be somewhat diminished. Again, the serum after bleeding has less antiferment than normally, that is, the fluids reaching the focus would have less inhibiting substances than before. So, too, diminution in the alkali reserve would tend to increase the acidity of the exudate. There are, then, at least three alterations following phlebotomy that seem of importance in directly influencing the anti-ferment balance of the exudate in the direction of acceleration of proteolysis. In addition to these alterations, which have a special importance in lobar pneumonia, there is a general plasma-activation which seems definitely associated with hemorrhage, which the writers have previously discussed.

3. Myasthenia Gravis.—Charles L. Dana makes observations on 14 cases of myasthenia gravis covering a period of more than twenty-five years. Nine of these 14 patients lived on from two to seventeen years, thus giving evidence of a better prognosis than is usually furnished in this disease. This difference in the course of the disease Dana believes is due in part to the treatment given the patients, namely, massive doses of strychnine. Fifty per cent. of this series had prodromal seizures consisting of diplopia or other symptoms of oculomotor weakness, with or without some bulbar weakness. The disease cannot with certainty be diagnosed unless eventually it shows bulbar or eye symptoms, or unless without this the course of the disease shows remission or recurrence. The writer finds that after a patient has passed through a serious attack, later attacks are more amenable to treatment. In several of these cases myasthenic myotonia, a symptom not much referred to, was noted. In this series some confirmation is given the view that in myasthenia gravis there is a pluriglandular involvement.

4. Spinal Drainage without Lumbar Puncture: A New Method for Increasing the Penetration of Arsenic into the Spinal Fluid in the Treatment of Neural Syphilis.—Budd C. Corbus, Vincent J. O'Conor, Mary C. Lincoln and Stella M. Gardner base their observations on the finding of Weed and McKibbin that intravenous injections of hypertonic saline solution cause an initial rise in the pressure of the cerebrospinal fluid followed immediately by a marked fall in this pressure, often below zero, and also that there is noted immediately a marked decrease in the size of the brain. They believed this phenomenon offered a possible method for increasing the amount of arsenic that could be carried into the spinal fluid after intravenous injection. Therefore, one hundred c.c. of hypertonic saline solution was administered intravenously and six hours after 0.9 gm. of neoarsphenamine was given by the same route. The procedure was carried out in 28 cases together with observations on the spinal fluid. The spinal fluid pressure taken at the end of eight hours was found to be within normal limits. Arsenic penetrations following this method were found to be as constant as, or better than, any method that has been suggested up to the present time.

5. Nephritis and Urinary Calculi after Production of Chronic Foci of Infection: Preliminary Report.—Edward C. Rosenow and John G. Meisser report that they have performed a series of experiments in which the pulps of teeth in dogs were removed and the pulp chambers infected with freshly isolated bacteria from various diseases, among them nephritis and nephrolithiasis. The canals were then sealed with impervious dental cement. Catheterized specimens of urine were examined at intervals and in the experiments on nephrolithiasis *x*-rays of the kidney region were taken at intervals. Lesions developed in the kidneys of these dogs which were essentially focal in character. The type of cellular infiltration and other changes resembled closely those of acute interstitial nephritis. The general picture in the dogs was somewhat different from that of patients with advanced nephritis. However, the character of the lesions indicated that, if the experiments had been of longer duration, the picture might have become more like that of well advanced nephritis. Five of six dogs infected with streptococcus from the urine of patients with nephrolithiasis developed calculi; the sixth dog died too soon for stones to form. The finding in these dogs resembled those in patients in this condition. The writers are convinced that the causal relationship between the calculi and the streptococci inoculated into the teeth is established.

10. Acetylsalicylic Acid in Sodium Citrate Solution.—Paul Nicholas Leech has investigated the claim that acetylsalicylic acid may be dispensed in a solution of sodium citrate without decomposition of the acetylsalicylic acid. The experiments that he reports show that this is incorrect; that after four days the acetylsalicylic acid is broken down to the extent of 50 per cent; after nine days to 75 per cent., and that in seventeen days it is almost completely hydrolyzed.

3. Treatment of Tuberculosis.—Henry Spahlinger bases his method of treating tuberculosis on two different therapeutic principles according to the nature of the disease. These are (a) passive immunization and (b) active immunization. Passive immunization, or serum treatment, applies to acute cases. It aims at progressive disintoxication. Spahlinger claims that the different symptoms of intoxication are not due to varying manifestations of the toxin, but to different toxins, each of which is separately used in the preparation of

a "partial" serum. The various toxins which serve for the preparation of three types of "partial" sera are: (1) Antitoxins obtained by means of several exotoxins secreted by Koch's bacilli in the culture medium. (2) Anti-endotoxins, obtained by means of poisons derived indirectly from the bacillary bodies. (3) Antibacterial sera, obtained by injecting a horse first with dead and then with living microbes, the animal having been previously submitted to a long progressive and intensive vaccination. The proportion of these three types of antibodies present in the combined serum varies according to the type of case under treatment. For pulmonary tuberculosis there must be predominance of antitoxins, for surgical tuberculosis predominance of anti-endotoxins. The treatment of pulmonary tuberculosis requires, in addition, the administration of antitoxins and antibacterial sera against mixed infection. These are prepared from the principal pathogenic germs which grow in the tuberculous lesions of the lungs. The injections of antibodies are made subcutaneously two or three times a week, sometimes every day, or several times a day in acute cases. Passive immunity is of very short duration; therefore the treatment with antibodies has to be continued uninterruptedly until improvement has been obtained. Active immunization is applicable to cases of chronic afebrile pulmonary tuberculosis, to non-pulmonary forms and to predisposed cases. The leading principles of this vaccine treatment are: (a) To obtain immunity against tuberculosis by means of separate immunities conferred by different components of Koch's bacilli progressively applied. The different vaccines are given in a sequence which enables the organism to utilize them. (b) The maintenance of the strictest specificity of the antigenic elements. (c) The use of the bacillary endotoxins robbed of their ectotoxins. (d) The mixture of antibodies with some of the antigens facilitates active immunization and avoids undesired reactions. The treatment extends over a period of a few months, usually not more than six, and whenever possible should be carried out in a sanatorium, hospital, tuberculosis dispensary, or by a specialist well acquainted with the technique of active immunization. A number of cases are cited to demonstrate particular points in the treatment.

7. The Fixation Abscess.—A. T. Todd calls attention to a type of treatment little known in England, but much practised in France, that is, the fixation abscess produced by the subcutaneous injection of turpentine. The rational indication for the employment of the procedure would limit it to those conditions in which "phagocytosis" is believed to play a part in the process of recovery, and when there is reason to believe this is not progressing satisfactorily. At the present time the method is being employed in bronchopneumonia of the influenzal type and pneumonia generally. It has been used in other septicemic conditions, including the puerperal sepses, and in the treatment of encephalitis lethargica. When the abscess develops promptly after the injection the prognosis is good, and conversely, a failure to take, especially after a second attempt, is of very grave significance. The writer has treated nine severely ill cases by this method, supplemented only by cardiac stimulants. Most of the cases were chosen for the treatment because, after due observation extending over several days, it was considered that the patient was going down hill and that there was no hope for recovery by the usual methods of treatment. Of these cases only three died, and one of these died on the same day. If a suitable site is chosen and other suggestions carried out, the abscess may be induced without causing too severe pain.

14. The Rôle of Heredity in Thyroid Pathology.—Pierre Vallery Radot mentions and discusses briefly some of the conditions which have been described as standing in etiological relationship to disturbances of thyroid function, notable acute infectious diseases, tuberculosis, syphilis, alcoholism, emotion, traumatism, and certain of the conditions associated with the reproductive function in women. He comments on the frequency of the infections and of syphilis and the relative infrequency of exophthalmic goiter, and then develops the thesis that heredity takes a prominent part in the causation of thyroid affections, the transmission being by glandular tendencies rather than by any nervous inheritance or predisposition. It has been shown that thyroid disorder of parents determines in their offspring certain conditions such as rarity of birth, poor development, malformations of bone, shortness of life, and lastly, myxodema; the successful result of thyroid treatment has also been demonstrated. This knowledge of the rôle of heredity in lesions of the thyroid has, above all, a prophylactic interest. It permits at times of diagnosis of disorders in the parents which enables treatment of their children to be directed against the real cause of disease. It is important to treat parents showing even the least signs of thyroid affections because a very light thyroid weakness in the mother may give rise to a clearly characterized syndrome in the progeny, and vice-versa. Wet nurses should be examined from this point of view.

1. Certain Aspects of Pain.—Henry Head summarizes the known physiological facts regarding pain sensations and sets out some important points in their interpretation. He considers particularly pain of visceral origin. So long as the internal organs are discharging their functions normally the afferent impulses which they originate do not enter the consciousness. This Head explains by suggesting that the cerebral cortex, which is responsible for the discriminative functions of sensation, exercises a dominant influence over the lower centers, represented by the optic thalamus, whose reactions are impulsive and urgent. These impulse reactions may be evoked either by a noxious stimulus, which reaches a high enough grade of intensity to overcome the inhibition of the cortex, or by disease or injury interfering with the paths through which the cortex normally exerts its control. But even when no such interference exists there is reason to think that once the path has been opened and dominance of the higher centers overcome a weaker visceral stimulus will be followed by sensation, so that long-continued visceral irritation may give rise to pain from apparently inadequate causes. If the pain is extremely severe it may spread widely even in normal persons. Should a referred pain become chronic this forms an even more important cause for its diffusion. Menstruation, anemia, and debilitating psychological states, such as worry or emotional shock, may produce similar effects. Occasionally, central resistance to potentially disagreeable impulses is temperamentally so low that pain may occur without any obvious cause for peripheral stimulation. In such cases the order in which the phenomena appear does not follow rules that can be laid down for pain of visceral origin. However, much knowledge may be gained by a study of pains arising from visceral disease, though they cannot be interpreted without a knowledge of the relation of afferent impulses to the segments of the central nervous system. As an illustration Head cites the common condition produced by tension within the aorta which produces pain referred to the sixth and seventh thoracic and adjacent segmental areas. On the other hand diseased conditions of the aorta and the ventricle may be associated with similar areas higher up on the chest, or in the region of the third or fourth cervical. The explanation of this distribution is found in the embryological development of the heart. It is not usually recognized that tenderness, due to afferent impulses from some organ in the thorax or abdomen, may be accompanied by areas of tenderness in the scalp. The site of the headache and tenderness does not indicate directly the organ which is responsible for their production, but depends more on the segmental level of innervation of the painful focus than on the actual organ affected. Thus the

higher the areas of tenderness upon the trunk, the further forward will they be found upon the scalp and vice versa. This, Head points out, is an aspect of referred pain arising from visceral disease that has been unaccountably neglected.

3. **Observations on Secretions into the Stomach and Duodenum with Special Reference to Diabetes Mellitus.**—T. Izod Bennett and E. C. Dodds have been able to establish by a series of observations on healthy men that the rise of carbon dioxide tension following a meal corresponds very exactly to the extent of acid and alkali into the stomach and duodenum. Confirmation of this is given by the curves of alveolar carbon dioxide pressure from subjects with varying degrees of gastric secretion, or with pancreatic insufficiency. Further confirmation is supplied by the results of experimental introduction of food direct into the duodenum. The application of atropine to the mucosa of the stomach or duodenum appears to arrest the secretion of acid or alkali into the organ to which the drug is applied. The writers believe that, like salivary and gastric secretion, pancreatic secretion must be a slow continuous process interrupted by a more vigorous flow whenever food traverses the pylorus. The fasting level of alveolar carbon dioxide tension in any subject represents a balance between the continuous loss from the blood stream of acid via the stomach, and alkali via the pancreas and duodenum. Cases of severe diabetes frequently show a slow fasting level of alveolar carbon dioxide tension even when no ketosis is present. Cases of severe diabetes investigated by the writers have, after a test meal, shown a fall of alveolar carbon dioxide tension greater than that seen in any other condition so far examined. It is suggested that this is due to a condition of hypersecretion of the pancreas, analogous to the gastric hypersecretion seen in cases of Reichmann's disease.

5. **Asthma and the Radium Menopause.**—J. N. McBean Ross reports the case of a woman 47 years of age in whom the menopause was artificially induced by the introduction of radium into the uterine cavity. This was followed by exceedingly troublesome asthmatic attacks and a purulent secretion from both antra. The patient gave a history of having had an operation on both maxillary antra for acute suppuration in 1906. It was assumed that the asthma was an anaphylactic condition caused by organisms from the nasal discharge. The nose and antra were put thoroughly in order and autogenous vaccines administered without any improvement as to the asthma or the patient's general condition. Every endeavor was made to find the cause of the asthma and every known treatment tried without avail. Finally, when a fatal issue seemed imminent, thinking that the menopause might be a factor in the condition, the patient was given by the mouth ova-mammoid compound, consisting of ovarian extract 1 grain and mammary extract 1 grain, four times daily. The result was both unexpected and striking. On the following day the asthma and bronchitis, which for a year had never been absent, were markedly improved; by the third day the asthma had entirely disappeared. The woman at the present time was to all intents and purposes cured. In asthma two factors may be at fault and both must be treated to obtain a satisfactory result.

3. **The Treatment of Cardiospasm.**—N. Mutch mentions some of the methods that have been employed in the treatment of cardiospasm and states that in the fully developed disease, permanent and complete relief can only be obtained by paralytic dilatation of the cardiac sphincter. Stretching must be so severe as to paralyze the muscle temporarily, much in the manner as temporary paralysis of the sphincter ani is secured by stretching in the treatment of certain diseases of the rectum. The earliest attempts to accomplish this were made from below the diaphragm at laparotomy. The best method, however, is to introduce a rubber bag into the upper orifice of the stomach and then distend it until the sphincter has been sufficiently stretched. A gum-elastic esophageal tube is used, which is closed at the lower end, but perforated laterally two or three inches from the point. Over these holes a rubber bag is fitted and is prevented from overdistention by a stout silk fabric incorporated in its walls. At lower tensions the bag is narrower in the middle than at the end, so that it does not tend to slip out of position after it has been inserted through the cardiac orifice. At higher tensions it becomes widest in the middle, and so exerts its greatest distending action at this point. At the upper end of the tube a small stopcock is fitted. At the lower end is a metal olive pierced for the reception of a silk guide. Water is chosen as the distending medium because, at the pressure used, its volume remains constant. In the event of the bag breaking no explosive force is brought to bear on the esophagus such as would follow the rupture of a bag of compressed air. The most convenient source of pressure is the water main, and the pressure can be measured by attaching a manometer. The pressure should be equal to about twenty-four feet of water. The procedure of dilatation is carried out with the patient seated before an *x*-ray screen so that the bag may be properly located half way through the cardiac orifice. The prospect of permanent cure which this method offers is very great. The best records are those of Plummer, who followed up the subsequent histories of about 100 cases of severe, uncomplicated cardiospasm, treated by forcible dilatation. Eighty-one per cent. were completely cured; 12 per cent. were partially relieved, and the remainder could not be traced or had died of intercurrent disease.

5. **Nonthyrotoxic Goiter.**—E. G. Slesinger points out that while malignant goiter is far from common, it is a most interesting condition in that the pathology of some of the varieties met with is as yet far from clear. Ninety per cent. of the cases develop in a preexisting goiter, and more than 60 per cent. of the patients are over 40 years of age. The epithelial tumors are particularly interesting, some of them being very much on the borderland between innocent and malignant growths. He tabulates these as follows: (1) Carcinoma, when it occurs in the thyroid, forms a hard, nodular tumor, very like carcinoma mammæ, both to feel and on naked-eye section. It behaves very much like carcinoma elsewhere, metastasizing by way of the lymphatics, and its sole peculiarity is a decided predisposition to form secondary deposits in a bone. (2) The so-called malignant adenoma is a curious tumor which occurs in a single nodule of growth. It is soft and cuts like marrow, and on section shows large polyhedric fields of cells, with numerous sinusoid blood-spaces. The vesicles are irregular, and lined usually with one layer of cells, in close relation to the blood spaces. The growth tends rapidly to invade the veins, and the whole picture is very similar to a section of the developing organ. (3) Metastatic colloid goiter is an extremely rare condition, which is of very doubtful malignancy. Histologically the gland is indistinguishable from ordinary colloid goiter, and the sole unusual feature is its metastasizing power. It spreads by the vascular route, and is prone to form deposits in the bones. Even when these occur, however, cases have lived as long as 17 years. While there is insufficient evidence by which this form of goiter can be satisfactorily grouped, it would appear probable that it is incorrect to include it among the malignant growths of the thyroid. The secondary deposits in this condition have been shown, in some cases, to secrete what is apparently normal thyroid secretion. (4) Parastruma is an interesting and rare tumor in which a hard nodular mass forms in the thyroid, grows rapidly, and speedily becomes adherent to surrounding structures. It forms secondary deposits, and runs a rapid course. Albert Kocher has shown that the cells of this type of tumor contain a considerable amount of glycogen, and considers that they are derived from remnants of the parathyroids. (5) Post-branchial goiter has been described as a distinct variety of tumor, but it seems doubtful

whether it does constitute a definite type. It is said to form large irregular nodules sharply outlined from the rest of the gland, and of rapid growth. Its cells are large and have the appearance of liver cells, the tumor being said to be derived from the post-branchial bodies. (6) The malignant papilloma is usually small in size, and either solid or cystic. It is arborizing in structure and sometimes contains colloid. It behaves like ordinary carcinoma, metastasizing in the lymphatic glands, and is of considerable malignancy. (7) A curious type of tumor which occurs occasionally and is termed cancroid, is of doubtful thyroid origin. It is never very large, is extremely hard, and has an irregular surface. In section it is white and granular, and typically like the epitheliomata. It always occurs on the same spot, and early perforates the trachea in the neighborhood of the first tracheal ring. It would appear probable that this growth is derived from the epithelium of the pharynx or possibly from the thyroglossal tract. The treatment of malignant tumors of the thyroid is most unsatisfactory, the disease having usually invaded surrounding structures before it is diagnosed. The prophylaxis of malignant disease of the thyroid offers the most hope, and consists in operating on all goiters which resist medical treatment.

3. An Experimental Study of Phagocytosis in Relation to Terminal Infections. Howard B. Cross.
4. The Chemical Dynamics of Muscle. F. Gowland Hopkins.

1. The Radiographic Evidence of the Influence of Cod-Liver Oil in Rickets.—E. A. Park and John Howland present a study based on 50 cases of rickets treated with cod-liver oil in which the results have been uniformly consistent. They feel justified in saying that cod-liver oil brings about a change in the bones which, if the diet be not too faulty, amounts to complete cure. The change is not noticeable at once, but is readily demonstrable in almost all cases at the end of a month. In two or three months so much infiltration with salts has taken place that the extremities of the bones, except for deformities, are practically normal, and only differences in the finer architecture of the ends of the bones indicate the previous existence of a rachitic process. They look upon cod-liver oil as a specific for rickets. They have not seen it fail in any single instance and have known it to cure rickets even though the children were dying of some other disease. They declare that they know of hardly another drug that in disease exerts so regular, certain and specific an effect as does cod-liver oil in rickets. The amounts of cod-liver oil administered varied from 2 to 4 c.c. three times a day. The article is illustrated by a number of interesting radiograms.

2. Lipodystrophia Progressiva. With Report of a Case.—Henry Lee Smith reviews the literature on this subject and reports a case of lipodystrophia progressiva in a woman 30 years of age, associated with arteriosclerosis, chronic nephritis, hypertension, and a moderate thyropathy as shown by the slight enlargement of the thyroid gland, the slight lid lag, the tremor, the slight nervousness, the increase in the pulse rate, the acrocyanosis, and the accelerated metabolic rate. The condition began to develop when the patient was 14 years of age. Lypodystrophia progressiva is a relatively rare condition, beginning insidiously and usually in early life; caused possibly by endocrine dysfunction; not hereditary; does not endanger life; and is more commonly and characteristically developed in the female. It is characterized pathologically by a slowly progressive, almost complete and probably permanent disappearance of the subcutaneous fat from the head, face, neck and upper extremities, and from the trunk as far as the pelvic bones and groin folds, and, especially in the female, by an increase in the subcutaneous fat of the buttocks, thighs and legs. Treatment has been unsuccessful. It has included the administration of thyroid, pituitary, and ovarian extracts, massage, hydrotherapy and overfeeding.

3. An Experimental Study of Phagocytosis in Relation to Terminal Infections.—Howard B. Cross was led to make this investigation because of the instances of energetic phagocytois frequently observed at autopsy. The surprising number of bacteria found within the leucocytes in individuals dying of fatal infection or intoxication suggests the possibility that the diminution of phagocytic activity sometimes associated with destructive infections may not be nearly as universal as commonly supposed. The data presented in this paper are selected from a study of 85 cases of infection which resulted in death and include a wide variety of both spontaneous and induced infections.

3. Diagnostic and Therapeutic Value of Lumbar Puncture in Lethargic Encephalitis.—George H. Hauser found the spinal fluid in his cases of encephalitic clear and usually under considerable pressure. There was no coagulum or film formed on the fluid standing. The cell counts were normal or showed but a moderate pleocytosis. In none of the cases studied did it exceed 11 per cubic millimeter. The prevailing cell was the lymphocyte. Globulin was not increased in any of the cases. All fluids gave a positive Fehling's test. The Wassermann was negative in all cases. The colloidal gold reaction was negative. This confirms the belief that the spinal fluid increase is the result of hypersecretion and not exudative in character, as meningitis always produces a curve in the meningitis zone. In the writer's cases it was noted that following spinal puncture and drainage of the canal, immediate beneficial results followed, irrespective of other therapeutic measures. The improvement in some cases was continued without further withdrawal of fluid. In two cases it was necessary to repeat the puncture and drainage to hasten recovery. It was noted, however, that the patients in whom it was necessary to puncture more than once did not relapse to their former mental state, but remained stationary, which condition necessitated further drainage. In some cases as much as 40 to 50 c.c of fluid was removed at one time.

10. Some Fractures of the Base Treated by Repeated Spinal Punctures.—L. B. Crawford advocates spinal tappings in the treatment of fractures of the base, though he does not claim that it is the ideal method of treatment in all cases. He contends that the treatment is well within the reach of all of us, and that if done repeatedly and enough fluid is withdrawn, the intracranial pressure will be relieved and much good will follow. It is really a spinal decompression and drainage, and where there is no blockage at the foramen magnum, the spinal pressure will be relieved and subsequently the intracranial pressure, too. He makes it a rule to do a spinal puncture in all head injuries, whether a fracture is suspected or not; it will do good in concussions, contusions, or basal fractures. In no one of his 10 cases did he puncture less than three times, and in three severe cases he punctured six times. All of his cases recovered. He believes William Sharne has taken the proper stand in these cases, when he claims that the majority of basal fractures, in fact, two-thirds of all cases, do not have an increase of intracranial pressure of more than 12-14 mm., as registered by the spinal mercurial manometer, and as long as this is true, spinal punctures will suffice and that decompression operation is unnecessary. If the pressure is over 16 mm., a decompression should be done immediately.

Book Reviews.

SEX. FOR PARENTS AND TEACHERS. By WILLIAM LELAND STOWELL, M.D. Fellow of the New York Academy of Medicine and of the American Medical Association; Member of the New York State Medical Society; the New York County Medical Society; Society of Alumni of City Hospital; West End Medical Society; Formerly Instructor in Diseases of Children, New York University Medical College; Attending Physician to New York Congregational Home for the Aged; Formerly Consulting Physician to the New York City Children's Hospital and Schools; Author of Articles on Children in the New International Encyclopedia, Second Edition; Many Medical Papers; and the Doctor Outside of Medicine. Illustrated. Price $3.00. New York: The Macmillan Company, 1921.

THIS is a very clearly compiled work on the ever-interesting subject of sex. It nicely covers the ground and the type of people for which it has been written. It might seem to some of its readers to carry a little too much sentimentality in certain of its phases, while in other parts of the book it impresses one as needing more vitality and energy. It is not the perfect work on sex—that book has not yet been written—but it is an exceedingly honest presentation of our knowledge on the subject, scientific facts or collected experience. One cannot shake off the impression that the author must have viewed sex life through very mild, even tempered spectacles which certainly could not have seen the tempests surging through some types of hot blooded humanity.

THE HEALTH OF THE INDUSTRIAL WORKER. By EDGAR L. COLLIS, B.Ch., M.A., M.D. (Oxon.), M.R.C.P., (Lon.), M.R.C.S. (Eng.). Mansel Professor of Preventive Medicine, Welsh National School of Medicine; Member of Industrial Fatigue Research Board; Late H.M. Medical Inspector of Factories, and MAJOR GREENWOOD, M.R.C.P. (Lon.), M.R.C.S. (Eng.). Member of Industrial Fatigue Research Board; Reader in Medical Statistics, University of London; Late Statistician to Lister Institute; Head of Medical Research Branch, Ministry of Munitions; Containing a Chapter on RECLAMATION OF THE DISABLED by ARTHUR J. COLLIS, M.A., M.D. (Cantab.), M.R.C.S. (Eng.), D.P.H. (Durh.), Medical Superintendent, Ministry of Pensions Hospital, Leicester; Late Temp. Lieut.-Col. R.A.M.C. With an Introduction by SIR GEORGE NEWMAN, K.C.B., D.C.L., F.R.C.P. Price $7.00 net. Philadelphia: P. Blakiston's Son & Co., 1921.

SIR GEORGE NEWMAN, who contributed the introduction to this comprehensive study of the hygiene and health of the industrial worker in England, says in part that Professor Collis and Dr. Greenwood have given something of an interpretation and philosophy, something of a new foundation, of the science and art of preventive medicine as related to the industrial worker. "Our record is a remarkable one from the beginning of the industrial revolution to the present day. . . . Again the crucial matters—hours of labor and their distribution, the effect of personal welfare, the effect of the occupation itself, and nutrition —find a place in the front rank of the subjects dealt with in this book, and thus the approach is personal rather than by external sanitation, important though that is. Thirdly, there is brought into bold relief the place, socially and economically, of the employment of women; and lastly, this book almost breathes with the spirit of the solidarity of industrial society; the interdependence between employer and employee, the status, wages, equipment and surroundings of the worker in relation to his health and that of his fellow men."

Beginning with a history of industry from prehistoric times to the present; hygiene of the past and present, with the associated diseases of occupation; causation and prevention of accidents; industrial employment of women; labor turnover or industrial wastage; supervision of industrial health, and a chapter on reclamation of the disabled, this work most ably meets the present-day conditions and methods of their improvement in order to advance the health and happiness of the workers of the industrial world and at the same time to increase the amount of output of goods to be manufactured.

If one could persuade the average manufacturer to sit down at intervals and thoroughly read this book he would receive many surprises together with a considerable amount of encouragement to try to continue any lines of hygiene and preventive medical work he might have undertaken. It is not always the fault of the employer that more advanced conditions of hygiene are not given a trial. The industrial worker in these later years must be taught some of the sense of appreciation for the splendid methods which have been advanced for his health and comfort during the working hours. While there is much yet to be accomplished in this direction, the improvements can best be done when both sides show a spirit of co-operation and willingness, rather than an attempt on the part of the employer toward better conditions only to be met with the spirit of sullenness and the attitude that whatever is done for their benefit is theirs by right on the part of the employed. This work shows that it is the product of thorough understanding of the conditions with which it deals and deserves all the praise it will receive, for it is a splendid piece of co-operative writing.

THE DISEASES OF CHILDREN. By the late Sir JAMES FREDERIC GOODHART, Bart., M.D., LL.D., F.R.C.P. Eleventh Edition Edited by GEORGE FREDERIC STILL, M.A., M.D., F.R.C.P. Professor of Diseases of Children, King's College, London; Physician for Diseases of Children, King's College Hospital; Physician to the Hospital for Sick Children. Great Ormond Street. Price $10. New York: Paul B. Hoeber, 1921.

A BOOK that has passed through eleven editions in thirty-six years must be a worth while book. The author of the work died after the tenth edition had appeared, yet there is really no break between that and the present edition since Dr. Still had assisted in several of the previous revisions and thus knew the book almost as intimately as the author himself. The authors are well known to pediatrists as leaders in that branch of medicine in Great Britain, and American students and practitioners are to be congratulated in having this work made accessible to them, for next to studying abroad is the opportunity of reading the works of foreign teachers and of comparing their methods with those familiar to us at home. The book is well printed and illustrated, but is not so well bound, it being difficult, without breaking the back, to make the pages lie flat so as to be read without strain of the eyes.

BISMARCK, NIETZCHE, SCHEFFEL, MÖRIKE. Der Einfluss nervöser Zustände auf ihre Leben und Schaffen. Vier Krankheitsgeschichten, von Dr. med. A. MÜLLER. Bonn: A. Marcus & E. Weber, 1921.

THIS work hardly lends itself to a brief review, being on the order of the Biographic Clinics of Gould and other writers. The first two names are familiar enough to Americans, some of whom may be surprised to learn that Bismarck was an almost habitual physical and nervous wreck, continually going to pieces from overwork and for much of his life under the supervision of a medical attendant. They may also be surprised to learn that Nietzche enjoyed superb health much of the time although suffering much at other times. Both were men of enormous and tireless activity up to a certain point, when Nature seemed to give out. To refer any of Nietzche's morbidness of views to his physique or morale seems absurd. His final breakdown is attributed by some to paresis, but this does not seem to have been probable. Scheffel was a poet and dramatist whose neuropathic tendency was aggravated by overwork and excesses. He changed his occupation a number of times and tried various climates in his search for health. Mörike, like Scheffel, was constitutionally neurasthenic and made his way with great difficulty. He wrote many poems and short stories. The two last named subjects, who are little known in the United States, are evidently of very different neurasthenic type from that represented by the more prominent men, the endogenous factor being much more pronounced.

SECTION ON SURGERY.

Stated Meeting, Held November 4, 1921.

DR. SEWARD ERDMAN IN THE CHAIR.

Subacromial Dislocation of the Shoulder—Open Operation and Reduction.—Dr. FREDERIC W. BANCROFT presented this patient, a man who gave a rather unusual history and had rather unusual findings. The history was that the patient dreamed he was wrestling and then fell out of bed. Upon awakening in the morning, he was uncertain whether his falling out of bed was a dream or a reality. He was unable, however, to abduct his arm and it was held in a position of marked internal rotation. He was then treated for three weeks in an orthopedic clinic under the diagnosis of circumflex nerve paralysis. When examined by Dr. Bancroft there was considerable atrophy of the arm. It was held in marked internal rotation, and it was impossible to abduct it without moving the scapula. The head of the humerus could be felt immediately posterior to the glenoid cavity lying directly beneath the acromial process. The anterior lip of the glenoid cavity could be felt. An anesthetic was administered, the dislocation reduced, and the arm put up in a Velpeau bandage. When the bandage was removed, ten days later, it was found that the head of the humerus had slipped out again, and an open operation was decided upon. In looking up the literature, very little could be found in regard to the technique of open reduction of the posterior dislocation of the humerus. Operation, however, was not difficult. The mode of approach was by incision posteriorly and cutting across the infraspinatus tendon. This gave a beautiful exposure of the joint capsule. The rent was easily seen, the capsule was sutured, and the wound closed. The arm was placed at right angles to the body but in extreme external rotation and kept in this position for four weeks, when active motion was started. The operation was performed five months ago. The patient now had perfect motion. The atrophy of the arm had disappeared since beginning muscular exercises.

Pedunculated Hemangioma of the Liver.—Dr. HAROLD E. SANTEE presented this patient, 35 years of age, who was admitted to Bellevue Hospital November 17, 1920, complaining of metrorrhagia and leucorrhea apparently from subinvolution and chronic endometritis. Her history was that for seven years past she had noticed a small mass in the abdomen which had never given her any pain. At times she felt it beneath the right costal margin, at other times near the umbilicus. She had felt it frequently herself without finding it tender. For the past two years, however, it had seemed to increase slightly in size until it was now the size of a baseball. It had been accompanied by no symptoms whatsoever. Physical examination was negative except for the surgical condition. The abdomen was relaxed and flat. On inspection there could be seen in the right upper quadrant lying between the umbilicus and the right costal margin a mass which elevated the anterior wall slightly beyond the corresponding left anterior wall. On palpatation there was easily felt a mass the size of a baseball, hard, very well circumscribed, not tender. This mass could be moved from the right costal margin across through the mid-epigastrium and downward to umbilicus so that the major portion of the mass could even be pushed to left of umbilicus and again across to right side practically to the anterior axillary line. It gave the impression of moving in an arch. Contraction of the recti fixed it in no way. No connection with any viscus could be made out. The liver edge was palpable just below costal margin. It was thought to be a mesenteric fibroma. Operation was performed on November 20, 1920. A tumor mass the size of a baseball was found free in the right upper quadrant except for a small thin flap attachment 1½ inches in breadth to the inferior margin of the liver extending from gall bladder fossa to the right. The right margin of this pedicle was practically entirely peritoneum; the left margin contained some liver tissue. No large vessels entering the tumor could be made out but the pedicle was fairly vascular with small vessels. The tumor mass itself was entirely covered with peritoneum. It was of elastic hardness as though containing fluid in its center. Underneath the peritoneal covering were two or three small areas which appeared rather cystic to feel. There was no attachment to viscus other than the liver. The round ligament lay well to left of tumor. The gall bladder was normal. Exploration of colon and pelvis showed no pathology other than moderate enlargement of the uterus. The operation consisted in a right rectus incision through anterior sheath retracting the rectus outward, then through posterior sheath and peritoneum. The pedicle of the tumor was clamped and the tumor amputated. The pedicle was whip-stitched over with plain gut No. 2 for hemostasis, and the wound closed. The report from the pathological laboratory showed the growth to be a pedunculated hemangioma of liver. The patient was discharged on December 3, 1920, the wound having healed perfectly and convalescence having proceeded without event.

Ochronosis, Associated with Ulcers of the Leg, Self-Treated by Carbolic Ointment for Over Twenty Years.—Dr. SANTEE presented this patient, a woman 56 years of age, admitted to Bellevue Hospital on February 29, 1921. She gave the following history: In 1892, following the birth of last child, she had swelling and edema of both legs, followed by an ulcer on the right leg. This was treated for four years with various ointments, but failed to heal as patient was active all the time. In 1896 an ulcer developed on the left leg. Due to failure of the ulcers to heal and their gradual increase in size she began treating them herself twenty years ago with carbolic ointment, first using the ointment only once a day, but liking its anesthetic effect on the ulcers gradually increased its use until on admission to the hospital she was redressing the ulcers practically every two hours and had been so doing for the past five or six years. Nineteen years ago, after using the carbolic ointment for a little over a year, she noticed the appearance on her forehead and over her cheek bones a bluish ink-like discoloration. In the course of the following five years this gradually appeared over the ears, knuckles of the hands, and about the elbows. The whites of her eyes showed blackish discolored areas. During the past six years the areas over the forehead and over the cheek bones had gradually lost their bluish color and had become brownish in color. Similarly small areas on neck, chest and forearms had assumed a brownish color. At no time had the patient suffered from any physical disability outside of that attached to the ulcers of the leg. Coincident, however, with the disappearance of the bluish pigmentation from the forehead and cheek bones, she noticed a marked increase in the pigmentation on her hands, both on dorsa and on the palms. The ulcers in spite of the use of carbolic ointment gradually increased in size, became very painful, and disabling. Examination showed the bluish black pigmentation involving the cartilages of the ear; slightly in the cartilages of the nose; markedly involving the skin over the dorsum of the hand, especially in the region of the knuckles, and well marked in the palms of the hands; also small areas over the elbows. The sclera of each eye showed a similar pigmentation, brownish black in color or either side of the cornea. There was a deep brownish pigmentation of the forehead, nose, and cheeks, in fact involving practically the entire face and extending down over the neck and chest. The forearms were similarly brownishly pigmented. The arrangement of this pigmentation was definitely symmetrical and seemed to lie in the deeper layers of the skin as well as in the cartilaginous portions where these were directly subcutaneous. A small segment of skin was removed from the dorsum of the hand for pathological examination, which showed a brownish pigmentation of many of the fibroids in the subepithelial tissues. The discoloration gave a smooth appearance to the fibroids. No granules were visible. The urine on repeated examinations was found to be negative for alkapton or carbolic acid, although the first specimen on admission showed a slight smokiness on standing for a short time. *X*-ray examination of the hands on March 10, 1921, showed atrophy of the bony structures of the

hand but no productive or destructive osteoarthritis. A similar condition of the knee joints showed on *x*-ray examination. The patient was kept in bed with red wash dressings for a few days, then Dakin's solution was used, and the ulcers improved markedly for a time and operation was recommended with the hope of getting a greater blood supply through the calloused base of the ulcers on which skin grafts could be placed. This procedure she was averse to, however, and left the hospital only improved. Her subsequent course since this time had been a return to the carbolic acid ointment with a marked deepening of the ink-like pigmentation on her hands and perhaps an increase in the size of the scleral pigmentation as well. In 1866, under the title of "Ochronosis," Virchow described a condition characterized by the deposition of brownish, blackish, or bluish-black iron pigment particularly in the cartilaginous structures of the body but also in tendons, joint capsules, periosteum, and certain internal organs, this pigmentation standing in close relation to melanin. Pathologically the costal cartilages, the intervertebral discs, the articular surfaces of large joints and the rings of the trachea were almost constantly pigmented. Occasionally the intima of the aorta and heart showed pigmentation. In the cartilages, the deposit of the pigment took place in the matrix, capsules and cells being spared or only slightly affected. In a considerable number of cases, ochronosis was attended by destructive lesions in the larger joints, sometimes giving rise to symptoms comparable to arthritis deformans. In about half of the cases, the urine was characterized by the presence of homogentisic acid or alkapton. This homogentisic acid being derived chemically from the incomplete breaking down of the protein in metabolism, particularly tyrosin and phenylalanin. Dr. Dakin, who had worked much in this subject, held that the homogentisic acid might be an abnormal product of metabolism rather than an intermediate product in normal metabolism. In about half the cases of this metabolic disturbance that had come under observation, a history of the long continued use of carbolic acid as a dressing had been noted. Whether this so influenced protein metabolism as to cause the formation of homogentisic acid in the tissues and its liberation through the urine, had not been determined. It was interesting to note, however, that normal cartilage immersed in a dilute solution of homogentisic acid would take on the same blackish or brownish black pigmentation that was shown in this type of case. No patient had been known to die as a result of this metabolic disturbance and it seemed not incompatible with a long life.

Dr. Harold Neuhof stated that Dr. Pick of Berlin had been very active in the study of ochronosis. When he visited Pick's museum he saw among his osteological specimens about a dozen showing this condition. The same type of discoloration exists in the bones as in the skin and particularly in the epiphysis and at the epiphyseal line. There was also a specimen showing pigmentation deposited in the large bowel. In some patients who showed but little discoloration of the skin one might have the diagnosis established by proctoscopic examination.

Dr. Erdman asked how early in the course of the development of symptoms the wrist drop was noticed. As he recalled, Dr. Aschner had mentioned the wrist drop as an early symptom observed before the diagnosis of thrombosis was made. In that case he wondered if it might not be related to pressure while the patient was on the operating table. It was possible that the intima of the artery might have been injured at that time, thus predisposing to thrombosis at this level.

Embolism of Brachial Artery Complicating Acute Appendicitis.—Dr. Paul W. Aschner presented this patient, a chauffeur, 34 years of age, who was admitted to the surgical service of Dr. Beer at the Mt. Sinai Hospital on February 14, 1920. Two days before admission he was seized with general abdominal pain accompanied by vomiting, fever, and chills. The pain then localized in the right lower quadrant. The man had had bronchitis nine years ago, influenza two weeks ago, and for the past two years a morning cough with production of a small amount of greenish mucus. On physical examination the findings indicated acute appendicitis with abscess. Because of the history of respiratory trouble Dr. Aschner began the operation under local anesthesia, later supplemented by light chloroform anesthesia. Through a three inch rectus incision a large pelvic abscess was evacuated. The appendix was found adherent in the pelvis, completely gangrenous, with perforation abscess of the mesenteriolum. The appendix and most of the diseased mesenteriolum were removed in the usual fashion. A tube drain was placed in the pelvis and the wound closed in layers. The patient progressed in ordinary postoperative manner until the third day, when he complained of sudden pain in the right arm and hand and increasing numbness of the fingers with inability to move them freely. On examination the hand appeared mottled and dusky in color, felt cold, and was definitely hyperalgesic. No pulse could be felt in the radial artery nor in the brachial at the elbow. A pulse could be felt, however, at the junction of the lower and middle thirds of the upper arm. A diagnosis of embolism of the brachial artery was made. Two hours later the point of pulsation had receded to the junction of the middle and upper thirds of the brachial artery and operative intervention was decided upon. Under local anesthesia Dr. Buerger exposed the brachial artery in its upper third through a four inch incision. The surrounding nerves were carefully separated, the vessel isolated and controlled by a traction tape. A half inch incision was made into the vessel just above the point of closure and a thrombus was milked up from below. Retrograde bleeding occurred. The vessel wound was sutured with silk, and pulsation being detected at the elbow the wound was closed without drainage. The thrombus was about 1.5 cm. in length, sterile, and showed beginning organization. The color of the hand improved immediately but it still felt cold, and the radial pulse was not restored. The whole arm was kept warm by an electric light apparatus. Paresthesias and pain continued, requiring the use of narcotics. The color continued to improve, but the thumb became blue, then black, and developed a beginning line of demarcation at the interphalangeal joint. The abdominal wound suppurated freely and there was some facial necrosis. Six days after the thrombectomy a tendency to wrist drop was noticed, and the neurological examination showed definite sensory and motor changes referable to the ulnar and musculospiral nerves. Although the brachial wound appeared to have healed *per primam*, there was some deep induration requiring wet dressings. On March 8, about two weeks after the thrombectomy, there was a chill and sudden rise of temperature to 105.4°, but the blood culture was negative and the fever disappeared in twenty-four hours. On March 12, a second chill and rise of temperature to 106° occurred and the blood culture showed hemolytic streptococci. On March 16, a considerable collection of pus beneath the healed brachial wound was found and evacuated. Two days later an abscess of the right tehnar space was found and evacuated. On April 7, demarcation of the gangrene of the thumb had become well defined and the terminal phalanx was disarticulated. The head of the second phalanx was rongeured away and the wound left open. In a few days the patient was discharged for further care in the dispensary. A month later he again come under observation. He was suffering intensely. His nights were sleepless. The hand and forearm were atrophic and rigid, the color was a dusky red, the fingers were purplish. There was hyperhidrosis. Neurological examination showed that while the musculospiral involvement had cleared up considerably there was marked impairment of the motor and sensory functions of the median and ulnar nerves. The amputation wound was not healed completely, the stump being tender and painful. *X*-ray examination showed two small sequestra. Wet dressings were applied and the bone fragments were extruded in the course of a month. Treatment of the neuritis was undertaken by Dr. B. Sachs who employed daily electrical stimulation. For the vascular phenomena the writer ordered postural exercises, the whole arm being extended above the head for a minute, then dependent for a minute, and then in semiflexion for three minutes. This was done three times a day for twenty minutes if possible. The results of this treatment was remarkable. In three months practically normal range of motion was estab-

lished. At the same time the atrophy of the muscles was overcome and the color and texture of the skin and nails approached normal. The vascular symptoms gradually disappeared and sedatives were no longer necessary. On September 7, seven months after the vascular occlusion, there was a fair radial pulse in the radial artery, which had persisted ever since. A month later the patient was able to resume his work as chauffeur and was now entirely well. Dr. Aschner said the case presented several interesting points. The source of the embolism and its course were puzzling. Various theories to account for these were discussed and the opinion expressed that the theory of paradoxic embolism was the most probable. The marked neural involvement was explained by the suppuration which developed in the brachial wound producing neuritis and perineuritis. Its effects were disastrous and rendered the limb useless. The remarkable result obtained by Dr. Sachs in its treatment was one of the most instructive elements in the case. The reappearance of the radial pulse after its absence for several months required explanation. Such a phenomenon could be due to one or two processes, either canalization of the occluded vessels, or the re-establishment of adequate collateral circulation by way of the superior profunda artery. The fact that pulsation could be felt in the radial artery for a distance of 6 cm. only, and that no pulsation could be detected along the course of the brachial artery below its upper third seemed to indicate that collateral circulation had been the method of recovery.

Experimental Reconstruction of the Esophagus by Granulation Tubes. (With Lantern Slides.)—Drs. HAROLD NEUHOF and JEROME ZIEGLER made this presentation from the Department of Surgery, College of Physicians and Surgeons, Columbia University. They stated that varied attempts by widely different operative procedures had been made to solve the problem of reconstruction of the esophagus after removal of segments of the organ. Briefly, it might be said that the earliest plan was the formation of a skin tube fashioned from the skin of the anterior chest wall, to which the esophagus above the stricture was attached superiorly, and the stomach below. Later developments consisted in the implants of loops of small or large intestine isolated in various ways and, finally, tubes or flaps from the gastric wall were employed for this purpose. Experimentally these methods had been followed by occasional successes and there were a few instances in which, clinically, too, they had proven satisfactory. In the human being such a procedure involved multiple operations over a period of many weeks or months with the ever present likelihood of failure from complications, as infection or gangrene of the isolated portion of the hollow viscus, etc. The technique was complicated and the patient must necessarily be in good physical condition to withstand the several major operations. If progress was to be made in this field it was essential to sharply differentiate the problem of esophagoplasty into two parts—a plan of operation adaptable for benign stenosis and one for cancer of the esophagus. In the former a considerable length of the organ might be involved or the strictures might be multiple; the patient was apt to be young and in good physical condition, and the problem was one of sidetracking and not of removing the disease. In cancer of the esophagus the patient was usually old and debilitated by the disease; and the problem was one of replacement of relatively short segments of the organ. It was the latter problem that had engaged their attention in the experimental studies. After referring to the methods employed in the two successful cases of reconstruction of the esophagus for cancer recorded by Dr. Lilienthal and Dr. Torek, Dr. Neuhof pointed out the fact that repair of a wound of the esophagus took place by granulation tissue. The impression that anastomosis between the esophagus and some other hollow viscus would be followed by repair as seen in the peritoneal cavity was incorrect. The esophagus had no serosal covering and the repair after operations upon the abdominal hollow organs depended primarily upon the existence of the serosal layer. Since repair of the esophagus took place by granulation, they had determined to make use of this fact by establishing granulation tubes between the esophagus stumps after resection of the organ. The experiments comprised a series of operations performed on thirteen dogs all under ether anesthesia. After trying various procedures they adopted the following operation carried out in two stages which they regard as the correct procedure. Fatal infection followed attempts to perform a one stage operation. A vertical incision was made to the left of the trachea and the esophagus was exposed by traction of the musculararure and great vessels. The vagi were stripped free, the branches going into the segment being sacrificed. The desired portion of the esophagus being thoroughly isolated, gauze packings were placed beneath it, the ends coming out of the wound. The latter was left wide open. At the second stage, one week later, the isolated portion of the esophagus was elevated by traction on the packings and was divided obliquely above and below. The packings and the segment of esophagus were then removed. A bed of granulation tissue was found to have been formed beneath the packings. A soft rubber tube of the diameter of the esophagus was securely sutured to the upper and lower ends of the organ by stitches passed transversely. The rubber tube had a lateral opening in order to feed the animal by a catheter passed through it into the stomach. When the tube became loose it was removed or had already been swallowed or discharged from the wound. By this time the external wound was largely closed by granulation tissue. An esophageal fistula, or rather a fistula through the new-formed granulation tube, persisted to finally close completely. Three experiments were described illustrating the process of gradual reconstruction of the esophagus by the granulation tube operation which indicated the results that had been obtained. A dog kept for seven months after esophageal reconstruction by granulation tube was in satisfactory physical condition during that period. After an early period of disturbed deglutition accompanied by repeated regurgitation of food this animal was able to swallow fluids and mush, but no large fragments of food. A stenosis of the esophagus at the site of the granulation tube was noted and it was apparent that this could have been dilated by bougies. However, this was not practiced because they wished to learn whether the stenosis would be progressive, and thus vitiate the operative procedure. The stenosis remained stationary and was found at autopsy to have resulted in the reduction of the normal circumference about one-fourth. Furthermore, the autopsy showed that the esophageal ends had been drawn together, reducing the original defect of 5 cm. about one-half. The lining by overgrowing epithelium was complete and the new formed esophageal tube was of the same thickness and of greater resistance than the adjacent esophageal wall. So far as the actual reconstruction of the esophagus by a granulation tube was concerned, they believed the difficulty would not be as great in the human being as in the animal experiments. The technique applied to the human being they believed should be through the posterior mediastinum by the extrapleural approach as described by Dr. Lilienthal. A string was attached to the tube, brought out through the mouth and anchored to the cheek so that the tube could be recovered when it became loose. The technique of rubber tube implantation which they described would appear to be applicable only to esophageal resection below the level of the arch of the aorta, and would probably have to be modified for tumors opposite or directly above the arch. From their studies they believed it justifiable to advocate the reconstruction of short esophageal defects such as those encountered in resection for cancer, by the granulation tube method they had devised.

Dr. WILLY MEYER said he was sure that everybody who had heard Dr. Neuhof describe these experiments on dogs would agree that they were not only interesting but likely of great importance. Some thoracoplasties, both extrathoracic and intrathoracic, had been done, and in some instances the lower end of the esophagus had been omitted and a gastrotomy done with the greater curvature of the stomach. In Dr. Torek's case the lower part of the esophagus was removed and the proximal end placed subcutaneously and connected with the gastrostomy by a tube. Dr. Torek's cases survived and took nourishment through this tube. Many

had attempted similar operations, but the patients had survived, at best, only a few days. Others had tried various intrathoracic procedures in animals. He had carried out some animal experiments. By means of laparotomy he formed the new lower portion of the esophagus from a portion of the major curvature of the stomach; then he did a transpleural thoracotomy, divided the esophagus, inverted the distal end, brought the newly formed lower part of the esophagus alongside the cardia through a slit in the diaphragm up into the posterior mediastinum, and united it with the normal proximal esophagus, which remained *in situ* undisturbed by end to end suture. Although certain of these one stage procedures might be successful in dogs in good condition, they were not suitable for patients with cancer; in such patients the operative procedure should be a two stage one. The work done by Dr. Neuhof and Dr. Ziegler marked a distinct advance in thoracic surgery. He believed their method would be of practical value even if a stricture was formed, because a stricture could be stretched by bougies. It seemed that by this method it would be possible to remove a growth and reconstruct the esophagus in such a way that its function would be preserved. Dr. Meyer said he could not refrain from speaking a word in reference to the *x*-ray and radium in this connection. With radium and the *x*-ray in tremendous voltage a number of observers had seen cures of epitheliomas of the skin and the question might be asked, if these agencies were efficacious in curing epithelioma of the skin, why they should not be used in treating epithelioma of the mucosa of the esophagus. He felt that if they could remove cancer of the esophagus by good surgery and could reconstruct the resected portion of the esophagus by a granulation tube, he would be in favor of the knife rather than of radium and the *x*-ray.

Fracture of the Femur: Analysis of Fifty Cases.—Dr. JOHN J. MOORHEAD presented this report on the surgical end results of forty cases treated by him at the Harlem Hospital and ten cases treated at the Post-Graduate Hospital during a period of nine months. An attempt was made to standardize the treatment based on such determining elements as general physique, site of fracture, and facilities for treatment. Statistics were charted giving the manner of accident, age, sex, method of treatment, period abed, and the condition on leaving the hospital. Before consideration could be given to methods of treatment, it was important to classify or "type" the fracture, irrespective of the level of the lesion, the physique of the patient, or the manner of receipt of the injury. This "typing" of fractures was the basis for all attempts at standardizing treatment, and closely allied to this fundamental consideration was the method of determining end results. In an attempt to classify the original condition, he had divided all fractures into two main groups, either of which might be simple or compound. Type I was the displaced malaligned or separated group in which the fragments were not end to end but were overlapped in their vertical or lateral axes. This formed the group called "typical." Type II was the non-displaced, the aligned, the non-separated group in which the fragments were end to end and not overlapped. These formed the group named "atypical." In fractures in which there was no such typing what might seem a "severe fracture" to one observer might be a "moderately severe fracture" to another equally good observer. End results offered some confusion as to definition. For the purpose of mathematical calculation, end results in fractures could be grouped under the three terms function, union, and contour. Function was allotted 60 per cent., union 20 per cent. and contour 20 per cent., thus realizing that function was three times more valuable than the other elements. After analyzing this series of cases and describing the various methods of treatment employed, Dr. Moorhead concluded as follows: (1) In fifty consecutive unselected cases there had been one death within twenty-four hours from associated fractured skull. (2) Twenty-eight of the cases were over and 22 were under 16 years of age. The average age of the adults was 51.2 years; the average age of the children was 6.7 years. The average age of the patients with facture of the femoral neck was 60.3 years; the youngest patient in this "neck" group was 49 and the oldest 75. (3) There were 35 males and 15 females. In the neck group approximately twice as many women as men were represented, namely 9 females to 4 males. Excluding the neck group, five times more males are represented than females; hence fracture of the neck of the femur was distinctly more common in women; but in the other anatomical zones fracture of the femur was definitely a lesion far more prevalent among males. Strangely enough, only 2 females were represented in a group of 22 children. (4) Excluding 14 cases in the neck zone there were 63 fractures in other zones; of these 16, or 44.4 per cent., were treated by the transfixion method and of these the nail remained *in situ* 29.6 days on an average. This indicated that by the transfixion method union becomes firm enough at the end of a little over four weeks to apply walking calipers or some other more or less ambulatory form of splintage. This confirmed his previously expressed opinion that the transfixion method hastened union very appreciably for by other forms of treatment in which skeletal traction was not employed union was rarely firm until the end of twelve or more weeks. Doubtless the increased self-massage, circulatory activity, freedom from atrophy, lack of edema, slight motion between the fragments and joint activity—all these incidental to skeletal traction—contributed to this early osseous repair. Approximately one half these cases were fracture of the middle third; approximately one-fourth were in the neck zone. Approximately one-eighth were in each of the other zones. In other words, approximately 88 per cent. of cases involved the upper half of this bone. Of these cases 22 had definite notes as to the extent of shortening at the time of removal of apparatus or at discharge; 19 of these had a shortening varying from ¾ of an inch to zero. Seventeen cases were recorded as having good results, and three had a poor result, meaning thereby that the limb would not support weight unaided. This series of typical cases would indicate that the treatment of fracture of the femur resolved itself into the following: (a) Children up to five years of age to be treated by overhead suspension. (b) Fractures of the neck zone to be treated by the abduction plaster of Paris cast, physique permitting. (c) Fractures in all other zones to be treated by one of the three forms of skeletal traction, of which the transfixion method was the choice.

Dr. EDWARD WALLACE LEE said this paper was most excellent and merited the consideration of everybody who was liable to be called upon to treat fractures or liable to be called into court, as so often happened, in connection with the results in fracture cases. There was good evidence that the treatment of fractures was not strictly in scientific hands, as one could see from the figures as to the results. Dr. Lee said he wished to emphasize one point in connection with the treatment of fractures and that was that fractures were treated too much, especially fractures of the femur. Surgeons were advising frequent *x*-ray examinations. For instance, he had seen from a country paper that Mrs. Smith of a country town had fallen and broken her leg. She was put in an automobile and taken a distance of twenty or thirty miles to be *x*-rayed, and was then brought back. A doctor had very little sense if he could not determine whether a leg was fractured or not without an *x*-ray examination. There were two or three things that everyone should recognize in the treatment of fractures. First, getting the fragments into position; second, keeping them in position, and third, using traction, especially if the fracture was one of the femur. Firm traction was the *sine qua non* for holding a fracture firmly in position. As to the traction apparatus, Dr. Lee said he knew of nothing better than Buck's extension. For many years excellent results were obtained with Buck's extension; to-day it was used very little, though one could look back and recall many fractures of the femur in which good results were obtained by the so-called ordinary splints, extension and sandbags, but there was not so much moving and carting the patient about. He felt that a great deal of harm came from moving the patient in order to make these *x*-ray examinations. Very often this moving brought about displacements which were

difficult to overcome. Dr. Lee complimented the paper very highly, but insisted that more care was needed in the treatment of fractures.

Dr. Seth M. Milliken said he had enjoyed the paper very much and would like to bring out one or two points. One was that children older than five years could be treated by overhead traction. Overhead frame could be used on children until they were too big, to be held between the bars or pulley high enough to have the pelvis clear from the bed. Nail traction was, to his mind, the most satisfactory method, the nail being surer to put in and easier to take out, and the nail never slipped. He thought the matter of promptness of making attempts at reduction had not been sufficiently emphasized, and advised that in all cases except fracture of the neck, an immediate attempt at reduction should be made by the attending or by the house surgeon in the absence of the attending, and if apparently successful the mobilization put on to be controlled by the subsequent *x*-ray unless one was immediately available. He presented an *x*-ray that had been made the following day of a case about which the house surgeon had phoned that no reduction could be done without an anaesthetic and that the patient was too large to go in the overhead suspension. Acting on orders the house surgeon had applied traction and immediate application of a plaster Paris cast from the toes to the hip, thinking that the reduction had been accomplished. *X*-ray showed an end to end apposition of the bones with very slight deformity. Dr. Milliken said that the *x*-ray was an absolute necessity for knowledge as to the control of the reduction and must be made in all cases, of course the *x*-ray apparatus was to be taken to the patient, and not the patient to the *x*-ray apparatus when that would be dangerous.

Dr. Willy Meyer agreed with Dr. Lee and Dr. Milliken that Dr. Moorhead's paper was a very excellent one. There were two points, however, of which he wished to speak, namely, the treatment of fracture of the femur in children and in very old people. Overhead traction in children was the correct treatment so long as it lifted the pelvis, that was until the child was six or seven years of age. If one put between the foot and the pulleys two large rubber tubes it gave a certain elasticity which the children liked and which permitted them to raise the body parallel with the limb and hip. In middle-aged people the Steinmann nail was no doubt the treatment of choice. However, in very old people he did not venture the Steinmann nail, but used Buck's extension with abduction, and started massage as soon as possible. He had the nurse give deep massage every four hours day after day. He had employed this method of treatment during the past summer in two women with fracture of the neck of the femur, one 74 and the other 88 years of age, and both made a good recovery. In elderly people, however, the Steinmann pin was best.

Dr. Howard Lilienthal also placed his approval on the Steinmann nail. He said it held the bone firmly and was very much less apt to do harm than any form of calipers. Regarding the cases treated many years ago, he had not seen as good results then as one saw at the present time, and he did not believe they had as good results as were obtained to-day. As to the people who lived in the back woods, light, portable *x*-ray apparatus was now being made and should find its way into the back woods. He did not think it was decent surgery to transport a fracture case over the roads just to find out whether there was a broken bone, and he did not believe there were many country doctors who would do such a thing. He did believe, however, that the Steinmann pin could be used outside the hospital and he believed that in fractures of the shaft of the femur it was the most valuable adjunct we had. If the patient was energetic, fractures of the neck of the femur, even in old people, might be successfully treated with an ambulant splint. He believed that treating these patients by putting them on an ambulant splint with crutches often saved their lives and in many cases saved a good limb also. The late Dr. H. L. Stimson used to be in favor of Buck's extension and he held that with Buck's extension there was a tilting of the pelvis so that it was not necessary to have the leg thrown out. Dr. Lilienthal used Buck's extension while waiting for the ambulant splints.

Dr. John F. Connors stated that for the past two years they had been treating fractures by skeletal traction. A Steinmann nail was first used on their service by Dr. Moorhead. They have become convinced that skeletal traction, however obtained, has proved itself to be the most successful device for the treatment of fractures. During the last year they had been experimenting with tongs and nail in treating fractures of the femur, and they considered that the best traction was obtained in the use of the nail. With this treatment the danger of ankylosis was almost completely obviated. The part was always open for inspection and massage, which did a great deal for early union and function. He thought that all fractures should be set as early as possible without waiting for *x*-ray, for in many instances much time was lost in waiting for the reports of the *x*-ray examination. They should be *x*-rayed after reduction, when one could see the result of his efforts. As to the treatment of fracture of the neck of the femur in elderly people, he advised an ambulatory splint and the patient allowed out of bed on crutches. By frequent *x*-ray examination one was able to observe the results, whether satisfactory or otherwise, in sufficient time to make any corrections necessary. He was of the opinion that the treatment of fractures should be by mobilization rather than by immobilization.

Dr. Seward Erdman mentioned that he had recently been at the Hospital for the Ruptured and Crippled, and Dr. Whitman had spoken of the fact that his method was sometimes condemned, when as a matter of fact most men in attempting to employ his method did not actually carry out his procedure. We often thought we were using the Whitman method but we did not get enough abduction. There were no dangers in the method according to Dr. Whitman. He showed him an old lady in plaster down to her toes yet she did not get hypostatic pneumonia. The head of the bed was raised and every two hours the nurse rolled the patient over on her face, using the plaster cast of the abducted leg as a handle. In this way the circulation of the lungs was not interfered with and the danger of hypostatic pneumonia was largely minimized.

Dr. Moorhead, in closing the discussion, said that in regard to Buck's extension he was sorry that in his hurry to read as much of his paper as possible in the short time allotted he did not emphasize a fact that he wanted to bring out, that was that in Type II cases without much displacement Buck's extension, or a plaster cast or a side splint would produce satisfactory results. The modern Buck's extension was the so-called military overhead frame, and except in compound and military fractures in which debridement was necessary and the muscles were paretic, they had never obtained satisfactory results with it. In the Type I fractures of the femur in order to overcome overlapping there was need of skeletal traction, and at the present time there were only three methods meriting consideration, namely, the transfixion nail, the tongs or callipers and the band or stirrup.

Adrenalin in Incoercible Vomiting of Pregnancy.—Rathery and Bordet appear to have made a striking discovery in regard to the action of adrenalin in the morbidity of pregnancy. The drug was administered by the mouth, by hypodermic injection, and by enema, always with the same result. The technique was somewhat complicated, the dose on the first day being 1 mg. hypodermically; on the second day 1 mg. each by mouth and by hypodermic injection, and on succeeding days the same until 8.5 mg. had been given in six days. Vomiting ceased at once, but lest this be attributed to suggestion the authors note that the organ becomes remarkably tolerant, so that anything in the way of food and drugs is readily retained. The tension of the blood is not increased until about the seventh day. Apparently there is a shortage of adrenalin in these subjects, and not until this is made up does the usual physiological action appear. The reader may be reminded that the pigmentations of pregnancy which so commonly appear also point to shortage of suprarenal substance.—*La Presse Médicale.*

Medical History.

NEW BOOKS AND OLD.

XXIII. WALTER MOXON AND HIS PILOCEREUS SENILIS.

By JOHN RUHRÄH, M.D.,

BALTIMORE, MD.

SOMETIMES one tires of the great things of the world and longs to turn aside for a little while to quieter, lesser subjects. So in medical bibliography I find it refreshing to turn away from the great names like Paré, Vesalius, Harvey, Servetus, and such giants of the intellect to little known names like, for example, Walter Moxon. But few of my readers know him or I miss my guess.

He did little in the way of advancing our knowledge of medicine, a number of papers contributed to Guy's Hospital Reports such as those on atheroma of the arteries, a contribution to the history of visceral syphilis, insular sclerosis of the brain and spinal cord, and the pathological nature of tumors and similar contributions, all very well in their way but not epoch making. His contributions were those of the average investigator and clinician.

He was born June 27, 1836, in the county Cork where birth control was not in fashion as he was one of nine children. His father was distantly connected with Edward Jenner of vaccination fame. His early education was not extensive and he was soon placed in a merchant's office in London, to which city his father had removed. The routine of business did not appeal to him and to get out of it he applied himself with industry and through his unaided efforts was able to pass the matriculation examination of the University, after which he entered Guy's Hospital in 1854, and with this institution he was associated the remainder of his life. In 1859 he got his M. B from the University of London. He was a brilliant, prize-winning student and in 1857 he was already an assistant demonstrator of anatomy. He used to urge his students to learn anatomy as he said he knew it, that is, as a cabman knows his way about London. After five years in anatomy he turned his attention to pathology. He was a gifted draughtsman and illustrated his work on "Pathological Anatomy," and left a large number of wonderful drawings of pathological lesions both microscopic and macroscopic. He contributed considerably to Wilk's "Lectures," the second edition of which he edited and greatly improved. He wrote numerous articles for the Transactions of the Pathological Society and published a series of "Lectures on Analytical Pathology."

From the pathological department he passed to the medical and became Lecturer on Materia Medica and Therapeutics. He was a brilliant lecturer and his hall was crowded with others than the students who came for mere instruction. Complimented on the large size of his class he replied: "I don't suppose I give the men better bread and meat but I put a little mustard on the sandwich."

He was characterized as hospitable, loving to gather about his board men of wit and wisdom. A "man of work-by-banter, of sparkling humor, wit, even to a stranger, by his slight oddities of manner and gesture, brimful of individualized nervous energy."

As a clinical teacher he was a distinct success, brilliant, suggestive, witty, but above all imbued with the idea that nothing could replace clinical observation, a part of medicine suffering somewhat in our day from our reliance on the laboratory and the Roentgen ray. Moxon once said: "The only use of books is to instruct you in the meaning of a name, your own eyes and ears and touch must teach you the nature of things."

His health towards the latter part of his life was not good, hemoptysis and hematuria, together with headaches and sleeplessness, led him to resort to chloral and he died from an overdose on July 21, 1886.

Perhaps I cannot end this part of my sketch any better than to copy the anonymous writer in the *Lancet* for August 7, 1886, which contained an obituary notice:

> That he was a physician of the highest type, well versed in literature, acute in observation, exact in diagnosis, and rational in treatment, all will be ready to admit; but when all the qualities that are essential to a great physician have been enumerated, and it is allowed that he possessed them in the highest degree, the picture fails to show in what his power lay; for Moxon's was a many sided intellect, and this induced men of every profession to think him best suited for the one to which they themselves belonged. Barristers envied his rapidity of thought, fertility in argument, and fluency of speech; men of science were struck by his perseverance, his industry, and his immense power of grasping details; dignitaries of the church, if sometimes slightly alarmed by the breadth of his views, recognized that his fervor and gift of persuasion might exert influence from the pulpit, and would have had him ordained. Yet no one could say that Moxon was lost in the medical profession; perhaps no other would have allowed such free play for so fresh and vigorous a mind. . . .
>
> Of late, under the pressure of friends and editors, he had, at intervals, contributed to the Contemporary Review, and perhaps we cannot end this sketch of his life better than by quoting the final words of his last published essay: "True, the vital spark of heavenly flame does somehow hold one together. Yet faith is not for the body, nor is hope mere earthly expectation, nor is life all centripetal, nor is the future merely a coming present; and those who vulgarize our holy things do harm to all that is noble in humanity, whose faith must endure all things, with 'nevertheless not my will, but Thine,' trusting ever in One whose ways are not our ways, who sees good in everything we call evil, so as to permit it, and evil in everything we call good, so as to send it quietly away, and believing that the good God is always good to all, and strives to be good through all to all, and never fails, but only seems to men to fail."

Moxon's contributions, apart from his scientific papers, are worth an evening's perusal. They were collected and published in 1887, after his death, under the title of Pilocereus Senilis, a pseudonym which he used to sign his contributions to Guy's Hospital Gazette. This I suppose may be translated into English as "The old white (waxy) poll," or "The old gray head." These "Notes and Reflections of Pilocereus Senilis" as they were called, appeared from 1873 to 1876. "I can't judge for young people now, but if you think these little pieces fit for a dull corner that by some strange chance might be found in your clever *Gazette*, these and more are quite at your service." So he wrote to the Editor.

He gave good sound advice; he rambled a bit here

and there with delightful comment. At the outset writing as it were to the medical student, he says:

Here's a melancholy truth! However you work your few ounces of brains, you will get out of them what Thomson and Johnson got with the few pounds their father left them. One pays in gold, another in brains. And the world will sum you up, not by the mite of store your exhaustion was able to give, but by the scrap it was when cast into the world's treasury. They will take you as they find you, and care nothing at all how you got to be what you are.

In one of the letters called "Truth and Negativism" he writes:

A golden thread has run throughout the history of the world, consecutive and continuous, the work of the best men in successive ages. From point to point it still runs, and when near you feel it as the clear and bright and searchingly irresistible light which *Truth* throws forth when great minds conceive it. Truth not of 'Fact' merely, but Truth that includes the world that your senses are too coarse for. . . . There is a power of living Truth where facts are dead—truth that cannot see whether the false is false, because the false never stands in his sight. He knows not the false; it burns away before him and is gone. But I forgot, some people don't distinguish between *things* and *truths*. *Perhaps you don't see that the constructive faculty of man has to make human truths out of brute things.* You don't think so! Ah! I see you don't apprehend truths that aren't things. You think there is no devil, do you? But look, there is no part of your life so really real as that in which the devil is a reality. These things we touch with our fingers are phantoms beside the devil's reality. They come and go, and you can pass away from and leave them. But the devil (*"Der Geist der stets verneint,"* the spirit which loves denial) you have always near you. Learn to fight him, and you will see how real he is, and what strength there is in victory over him.

In "Liberty and Waste" he refers to a good old English Bishop that we should like to have with us in this country today—that is some of us would.

Something in every Englishman's heart admires the good bishop who would "rather see his country free than sober." (Whether it is sobriety or freedom that moves this admiration we won't stay to inquire.) But in our worship of Liberty let us take into account the sacrifice a complete Liberty compels us to make. Let us look at the negative side of Liberty—what it takes away. Suppose all the youths grow up in personal freedom and self-dependence, and have no reliance apart from their own private judgment. What, then, do they lose? You will see that they lose the fruits of the greater part of their nature. How? Don't you see? Think, then, how much of each of us lies waste and unused because his individual motives don't furnish "go" enough to employ the powers he has. To use this waste (the larger part of most of us, by the way) it needs that one's individuality should come under some influence that shall carry it off from its self-centered Liberty), and occupy it in an honorable unreserved spirit in work, under what is greater and better than self; what I mean is, that as "free" individuals we have not power enough over ourself. I don't mean power to repress ourself—we can acquire that—but power to use ourself actively; a very different thing. How much of any man's wretched restlessness could be traced to the half-conscious striving of faculties he can't use. To use them he must go under some mind moved by greater purpose. A great enough purposer can use any man's waste powers—powers that are out of the man's own reach. But if he will remain in self-centered "Liberty" then that better social part of his nature which his self cannot move is lost to himself and to others. The best interpretation of human restlessness is the instinctive desire to be used for some strong purpose, some meaning greater than a man's own individual tendency.

From "The Thoughts of the Heart," the following are striking:

Perhaps that is as well; spying into the brain with the highest object-glasses is something like using extra big spectacles to examine the closed edges of a book you are to read, but cannot open. . . . The fact is, the brain is a sort of Æolian instrument of many strings whereupon the several organs play ("organs play" sounds as topsy-turvy as Polonius at supper where he was being eaten, but I cannot help it). There are no thoughts in the brain without the whirl of the blood through it, any more than there is music in an Æolian harp when the air is still; and the brain in its vast complex receives influences which stir it to action in various regions and manners according to the appetites and passions connected with the several functionary parts of the body, as many winds move upon the vast expanse of the sea. So that David was right when he said "the thoughts of his heart;" but the heart is not the only agent for eliciting thoughts from the brain; for while we say, "Out of the fulness of the heart," in reference to some, yet in other cases you feel sure you would be right in saying, "Out of the fulness of the stomach the mouth speaketh," or else out of an overfull muscular development of some other parts of the body. . . .

Now, practically, you see what a responsibility there is in having any organ over-active, hypertrophying beyond its just proportions, and hence playing too vigorous a tune on the nervous stringed instrument in your cranium, and how one must watch the energies of a dominant organ and withdraw from circumstances that rouse its too great activity. But it is not only in regard of individual organs that this is true; the danger of getting only thoughts of one sort, or too much of one sort, extends to a much higher sphere of activity. For instance, if you spend all your time in experimental processes of scientific weighing and measuring, you will come at last to think all nature is to be explained by the ponderable and measurable, as Professor Tyndall appears to have done. On the other hand, if you employ your time in the over-activity of the organization at play in religious emotion, that kind of emotion will determine the turn of your thoughts until you are ready to oppose the conception of order in Nature in which religious liberty and tolerance are grounded, as many of his opponents do.

In short, special kinds of activity determine character. Thus are we creatures of our own activities, and he who has no special activity will have no character.

From "Conversation" just one sentence which I should like to print and send to all the "holier than thou's" which infect our country.

True goodness is not the sort you pride yourself in and force upon others. True goodness is a thing ascribed to others, rather than felt inside, since the days of the Pharisee and publican.

With false and pretended culture Moxon had little patience and he takes his fling at the *worms* who cover themselves with intellectual scraps. I take the liberty of italicizing one part of the following:

Did you ever see a caddis worm? When I was fishing I never could stick a hook into a caddis worm. I never contemplate a caddis worm without a certain feeling of brotherhood. Nature is essentially too satirical in the way she takes off one thing when she designs another. Every one has, by nature, the faculty of picking up bits wherewith to furnish himself according to the grounds he is upon at the time, as the caddis worm dresses herself in scraps of green when she is upon the leaves, and in bits of brown when upon the stones. Don't despise the simile and think it rough. Don't say to me, "Everything has both its higher and lower parallels; why should our elevated minds take the lower parallels?" I should be tempted to reply, "To keep down at our proper level, O brother worms!" In point of fact, I expect, the mental dress of most of us is rougher by comparison with the best satins and velvets at Swan & Edgar's. *Most minds are like maggots dressed in scraps, and all that is their own is just the glue the scraps are stuck with; and so much is the weakness of even this glue recognized that in common*

conversation your subject must not be too deeply or seriously followed. "The human mind" won't endure it. In other words, you mustn't shake the scraps much for fear you see the maggot.

In "Nothing, a Protest against Buttermilk" he again states his ideas concerning books. One or two excerpts must serve:

But alas! there is a vast heap of trivial petty and fragmentary and doubtful generalizations which you will be made to learn in your great big books. Study well your books, but things teach more of you. Books tutor your reason; things tutor also at least your imagination, and if you are observant will store in you a fund for all your faculties, from fancy up to faith. Students must be fed on very concentrated intellectual food in their books, but the amount of it should bear some proportion to their time and powers. Soon they will be like so many maggots born so very deep in such very big nuts that the poor things never or rarely succeed in eating their way out to wings and daylight; perishing thus miserably short of a higher life because the supplies of their larval stage were too voluminous. Such abortive book-worms the colleges are trying to make you all. Help yourselves, or God help you! Read with judgment, and use your senses well. Your books have no right to do more than suggest, guide, and aid towards your work in the real world you are to become meanwhile a part of. The man who only crams his "mind" with the trivial generalizations that swell up your volumes too big gets a peculiar look of the species of dissipation that is quite characteristic. Blankish, awanting, abstracted, and with a certain unreadiness on the present occasion, whenever that may be—why, even the animal young man from the turnip-fields who hands about our Fives-Court is wider alive than he.

Of the great increase of printed matter he voices a sentiment which many of us have expressed somewhat differently. Had he lived today I wonder what he would have said,—perhaps what he did in 1876:

The cheap press pours out the crude details contributed by little people; and other people no greater, except as more voluminous, sweep up the details into books of ever-increasing size, from the last edition of your once portable classbook, through So and So's system of large books on medicine, up to Ziemssen's regiment of tomes. Heaven help you! Can a cheap press multiply your precious moments?

(*To be continued.*)

Glauber's Salts.—Glauber, born at Karlstadt in 1604, was a transitional figure between the alchemist and chemist. He believed in the philosopher's stone, elixir of life, transmutation of metals, and universal panacea, and other things to which modern science is returning, but he also had some notions of the science of his time, was familiar with the preparation and properties of numerous chemicals, and knew how to manufacture some of them, such as commercial niter, on a large industrial scale. He applied chemical knowledge to cookery, and could also make artificial gems. In 1658 appeared his book entitled "Opera Chymica," which, despite its title, was written in German. He had no classical education and, as far as culture went, was a primitive man. This lack of education reacted on him, as it had on others like him, and he was filled with vexation at himself and bitterness toward the learned. After having lived in Vienna, Cologne, and Frankfort, he died at Amsterdam in his sixty-fifth year. The discovery of the salt which bears his name was made during his sojourn in Vienna. He had complained of stomach disorders and lack of appetite, and had been advised to drink of a spring which was situated in the close proximity of vines. This was near Neustadt in Austria, and its virtues were attributed to niter. Improvising a cup out of bread, he drank of these waters and, as his appetite showed signs of returning, he kept up his visits to the spring, and eventually recovered. After having drunk the water, he finished by eating his cup of bread. The next thing for a chemist was to analyze the saline ingredients of the water. He soon showed that they did not include niter. The crystals of evaporation resembled ice in texture, being long, slender, and transparent. Thrown on a live coal, they did not crackle like salt nor burn like niter. Out of gratitude he named it *sal admirabile*. He identified it as sodium sulphate and chemists conferred upon it the name of the finder.—LECLERC in *La Presse Médicale*.

Opodeldoc Balsam.—This substance is rarely prescribed to-day, and possibly this neglect is to our disadvantage. The agreeable odor, the "pretty" appearance and mother-of-pearl effect, the unctuous feel, the warmth when rubbed into the arm, for example, make a combination of appeal to the senses not easily excelled. Moreover, it does not damage or stain delicate linen fabrics and is harmless to the skin—an excellent combination of *suaviter* and *fortiter*, for it may often produce the desired therapeutic effect. Perhaps no word has produced more speculation as to its etymology. It has been derived from the Celtic and Sanskrit, from the Low Countries, etc., etc. In Frisian patois *op en del* means up and down, and suggests its use by rubbing. Other derivations are more fantastic, although there is some agreement in deriving opo from the Greek *opos*, juice. The best expert testimony favors the coined word theory, and some would have it that Paracelsus himself coined it. The original significance was general or, in other words there were a number of different opodeldocs. Paracelsus gives an opodeldoc of the four gums and resins, an opodeldoc of cantharides and others of pine-pitch, rosin, old wax, ammonia, myrrh, etc., etc. In other words, an opodeldoc was at first a liniment. The opodeldoc of the French Codex of 1758, which contained 31 ingredients, was, however, not a liquid at all, but a plaster. The balsam, as used in comparatively modern times, is presumably after an English formula and after many years of change is found in the French Codex of 1818 with but six ingredients—soap, camphor, ammonia, rosemary, thyme, and alcohol, in other words, the linimentum saponato-camphoratum of the National Formulary. Thirteen other ingredients had been discarded from time to time. This fluid might also serve as a vehicle for chloroform addition, and in fact, for any addition at the practitioner's pleasure. Leclerc, from whom we quote the preceding, still uses it with addition of laudanum and tinctures of stramonium and mandrake.—*La Presse Médicale*.

Action of Ferments and Toxins on the Gastric Vagus.—Loeper and others call attention to the recent discovery in the laboratory that pepsin can obtain access to the branches of the vagus and diffuse therein. Experiments show that ingested tetanus toxin may travel along the nerves to the medulla. In these cases, however, the stomach has been ligated. He also found a pepsin-like enzyme in the medulla which was not present in the cerebrum. In certain diseased conditions of the human stomach it is probable that this factor might be superadded.—*La Presse Médicale*.

SLEEP

(NORMAL AND ABNORMAL)
AND THE MECHANISM OF SLEEP.

BY J. VICTOR HABERMAN, A.B., M.D., M.S.D. (Berlin),
NEW YORK.

THE recent pandemic of lethargic enceplalitis with its cardinal manifestation of drowsiness and sleep-impellance and the not infrequent complication of associated insomnia at night or as a sequella again focussed attention on the nature of sleep and questioned its origin, and exhumed old theories from desuetude theories which claimed a "center" somewhere in the brain, sustaining consciousness, hence keeping awake, or out-shunting it — thus causing sleep.

The most famous of such theories was that of Mauthner, who from the concommitance of somnolence and occular palsies in a triad of diseases inferred that the sleep switch must lie in the "superior" area of the brain stem in which the oculomotor nuclei were likewise imbedded. Disturbance here would enjoin sleep and invalidate the motor eye. In the very earliest of the publications on epidemic encephalitis, Economo, no doubt taking his clew from Oppenheim, brings up the Mauthner theory and fortifies it through this added instance of lethargy and occular symptoms in the new disease, and the pathological effects come upon in this very brain stem area. And following Economo, without exception, every writer on the subject here and abroad cites Mauthner—and gets no further.

To challenge this now widely acclaimed conception is both hazardous and bold; and yet a careful study of the matter easily discloses sufficient flaws to discredit Mauthner's and similar contentions and offers data for a more tenable theory, or at least a sequence of facts which will prove a stabler foundation to build on

The Theory of Sleep and the Sleep Center.—On the utility of sleep we need not dilate. The period is one for (cellular-phsiological) recuperation — wear-and-tear recuperation—and accumulation of energy (psychic energy).* During awakeness energy is consumed, through sleep it is replenished, though just how we do not know. Awakeness is synonymous with consciousness. Hence, sleep is a temporary suspension of consciousness, or, as the cerebral cortex is the seat of consciousness 2, 3; of this there is no more doubt, sleep is a temporary cessation of cortical activity. How is it accomplished? One may think of a depression or slowing of the activity, a dissociation of cortical areas or of the entire cortex, a blocking, or discommunication, etc., etc.

Thus, one knows that *association* or memory work by and by produces a fatigue—one feels the oncoming difficulty to associate, hiatuses and gaps occur —with these the bobbing of the head (breaks in the motor tone)—and finally . . . we do not "connect" again, but doze. Fatigue does it, or a fatigue *product*. By some it has been thought that this *product* or metabolism *by-product*, is formed in the brain cells*—by others that it originates in the muscles (through muscle work). Thus, lactic acid has been held responsible, again, Cholesterin, "Kenotoxin," Hypnotoxin, etc. Even in recent years the theory came into its own again by Bouchard,[6] believing he discovered the culprit substance in the urine.

Besides these endogenous products, we know of chemicals (alcohol, drugs) which, though they may first stimulate, soon slow up the associations—and finally provoke sleep. Their action is similar to that of the fatigue products, inasmuch as they produce sleep or sleep-like states, the milder ones really tending to bring on real sleep. Their after-effects, however, vary, vary immensely according to the particular chemical combination of the drug. As these after-effects (muddled mind, heavy, aching, blank feeling, etc.) are surely cortically occasioned, we may assume that the "fatigue

*By which we do not mean to say that cellular energy—and especially nerve cell energy—is the resultant directly or indirectly of sleep. This *energy* problem—when it comes to nerve energy—is very complicated (much stimulating matter on the subject will be found in Bechterew's "Psyche und Leben," to which we refer below). The strain of attention, however (and attention is the chief psychological girder of awakeness), is a constant drain on the physiological activity of the cells. After a period of psychological or physical activity, the *psyche* fags and finally "suspends." This may mean that the cells physiologically have been exhausted. Then comes a period of sleep, after which the *psyche* is again fresh and potent. Hence, we assume the sleep-period the physiological replenishing period. Though all the cells of the body participate, it is the brain cells which are mostly involved.

In this connection the experiments of Weygandt[7] are very interesting, for he found that the fatigue produced by different kinds of mental activity needed various lengths of sleep for recuperation. Thus, a half-hour or so was sufficient to neutralize the fatigue occasioned by an addition task, while five or six hours of sleep—or even more—were necessary in the case of a memorization task. Memory work, therefore, seems to prove a great strain.

*Thus, Ishimaris[4] injected the extract of brains of animals for a time held sleepless into other animals, and put these into a very "sleep-like" state. Mosso made a similar experiment, using the blood of an animal thoroughly fatigued and transfusing it into one having been at rest—getting the same results. Mosso's experiment would merely point to fatigue "products" in the circulation, not to their source.

products" also act on the cortex. The same is true of the "sleeping drugs" and the anesthetics. Yet these very after-effects of the exogenous products (somniferent beverages, chemical combinations called hypnotics, narcotics, etc.), so unlike the after-effects of normal sleep, and so varying, show that there is a great difference between the activity of endogenous and exogenous.* The *fatigue produets* theory is also weakened by the facts that over-fatigue hinders, rather than aids, sleep, and that the bedridden and individuals doing little bodily work, also, in spite of a lack of fatigue and "fatigue products," sleep. And doesn't the normal infant, who sleeps most of the day, also sleep at night? And, for that matter, the habit of sleeping, once established, do not children and adults fall asleep when bedtime comes whether they are still fresh or really tired? On the other hand, one might be nigh dropping with fatigue, and fright or danger will dispel it in an instant. (Cf. also on difference between normal and abnormal sleep, below.)

Another theory assumes a lessened blood supply —*i.e.* an anæmia of the brain. Thus, we know that the flow of blood to the stomach (and so away from the head) after a meal is sleep tending, also hemorrhage, or general anæmia and chlorosis. The sleep tendency in the obese is also attributed by Brugsch[8] to brain anæmia (though this explanation does not seem to us especially satisfying). Mosso[9] demonstrated the lessened blood flow to the brain during sleep, and so believed sleep due to a temporary undernourishment. Interesting in this connection is the fact that in infants the fontanells are found sunken in at this time. Direct observations have also been made of the brain during sleep in individuals with a skull opening (through accident or trephination). Dendy observed such a case, and found the brain sunken in and quiescent. When the individual dreamed, the brain rose some, while, when awake, it seemed full and turgescent. In trephined animals, an anemia has also been noticed during sleep (Durham). On the other hand, the very reverse has been thought to be the cause of sleep, namely, a brain plethora, and the reverse condition found on direct observation. Thus, J. Brodman[10] demonstrated a brain plethora, and A. Czerny,[11] in a child with a traumatic skull defect, actually saw the same. Finally, one has assumed an anemia of the cortex and plethora in the deeper brain or indeed in the brain stem (Pilcz). All in all, the evidence prompts us to conclude that neither anemia nor plethora has anything to do with normal sleep—and sleep may occur in, or in spite of, either condition. In the case of hyperemia, one would have to consider whether active or passive. Surely the active, as Wilbrand and Saenger remind us, cannot be especially inducive to sleep. And yet, in encephalitis, whether secondary or primary, there is a general brain *hyperemia.*

Some have thought a greater *fullness* of the brain through hyperemia causes sleep, the very position assumed (proneness) inducing intracranial fullness. (But is this arterial or venous? Very recently Erben[12] showed that the prone position, as well as squatting and bending the head forward, all cause a *venous* hyperemia in the skull.) Others have thought the fullness due to "osmosis" (*i.e.* water), the *pressure* causing the sleep phenomenon. But trephined individuals, with a lessened pressure, also sleep. On the other hand, intracranial pressure, as in cases of tumor or hydrocephalus, *does* cause somnolence. Increase of water in the brain cells themselves has also been suggested.

Various "metabolic" theories have been offered. In Mosso's, mentioned above, temporary lessened nourishment was presumed, through lessened blood supply. In Pflüger's[13] complicated theory a lessened intramolecular oxygen formation was postulated, the brain activity being supposedly due to the "exploding-like" change of this (in being used up) into carbondioxide. More recently Howell[13a] also assumed sleep to be caused by lessened cortical metabolic activity, due to decreased oxidation. These theories, however, do not account for the fact that, though asleep, one may nevertheless have cortical activity, as in dreaming, *parvor nocturnus,* sleep walking, even the most active and intense excitability during somnambulism.* The grinding of teeth, kicking with limbs, spasms of muscles, often *only* occur during sleep. Highly interesting is the account of Nanson, in his "Farthest North," that the cold would send one asleep while on the march, and that walking would be automatically continued, *though asleep,* until some obstacle or unusual condition would again rouse one. To these facts we might also add the induced hypnotic somnambulism, to which phenomenon we shall presently return. Still other metabolism theories depend upon a chemical interplay, which, when disturbed, causes insomnia. So R. Heinrich[15] recently made phosphorus dysmetabolism particularly responsible in this connection.

Nor have endocrine theories of sleep been wanting. Thus, the pituitary gland has been held especially accountable as the secretory source in some way or other governing the vegetative function of normal sleep (Salmon[16]), or abnormally as a pituitary dysfunction, giving continued drowsiness or impellance to sleep. True enough, states of somnolence have been seen in pituitary disease (hypopituitarism, tumor of the hypophysis, etc.) (cf. a recent MEDICAL RECORD article by Dana), but these do not explain normal sleep or the periodicity of sleep and waking. Some here contend, like Cushing, that it is not the pituitary disease, but the *pressure* exerted by the tumor mass which causes the symptom. Very different — and elaborate — is the endocrine theory of Sajous,[17] who, referring to Howell's work explains the hypometabolism as dependent on lessened *adrenoxidase* (adrenalin in combination with oxygen), and calls into play an "erection" mechanism of the cell dendrites ("gemmules"), producing when erected a "more exposed" area of myelin to the action of the oxidizing substance (adrenoxidase), and hence, more able to transmit nerve impulses, *i.e.* while awake; on the other hand, when the erections have collapsed or retracted, giving poorer transmission, *i.e.* in sleep. Sajous here takes over and builds on an interesting cellular theory of Lanoitte and Pupin, to which we shall presently return. Let us, however, first complete his endocrine theory—an intricately hypothesized process, which may be epitomized as follows:

The pituitary gland is the *regulator* of the endocrines. In the normal individual sleep is brought about through the sympathetic center (in the posterior pituitary), by

*Nevertheless, the very fact that these chemical combinations *do* produce sleep does bring up a similarity to the theorized sleep-producing fatigue-product, and lends something to the theory.[7]

*A remarkable series will be found in Loewenfeld's study. Two remarkable cases are also described by Lavele (l. c.), p. 12.

its sending constrictor impulses to the arterioles of the anterior pituitary and the thyroid, thus lowering the metabolic activity of the body. Vasodilatation follows in the splanchnic area and blood thus drawn from the peripheral organs, including the cerebrospinal system—hence, lessened metabolic activity in the brain, and diminution of adrenoxidase-laden plasma—and consequently inhibition of activity of the neurones. This causes unconsciousness (sleep). In the abnormal it might be so that a decreased adrenal secretion gives decreased adrenoxidase, and this occurs through depression of the adrenal center in the pituitary, brought about by the thryoid.*

Once or twice we have come upon a direct endocrine(opathic) explanation of the lethargy in epidemic encephalitis, but these were weak, and not offered with much vim.† This is surprising enough, seeing we are at the moment on the full-flow tide of an era of endocrine romancing, an era which might well be dubbed that of endo*crime*ology, with its forced interpretations, unproved reiterations and a harrowing literature almost (not quite, however) vying with the publicity-campaigning and hyperquantivalent assumptions of the now happily waneing Freudian movement.

The cell theory of Van de Lanoitte and Pupin, mentioned a moment ago, we have already written of elsewhere as a possible explanation of the hypnotic phenomenon.[20] It rests on the discovery of Golgi and Cajal that the end twigs of the neurone are not continuous with, but contiguous to, the adjoining cell, interlacing with its dendrites. The dendrites are ameboid, and so, extending, give contact and transmission, or, retracting, loosen and dissolve the conductivity, and in this way cause a partial or definite break in the neural flow (the nerve impulse)—thus explaining the phenomena of sleep, hypnosis and other strange psychic states. Closer entwining of the dendrites, on the other hand, would give better conduction; hence, clarity of thought, etc. Ramón y Cajal even held that on heightened functional activity new dendrite shoots might be sent out, and so form new collaterals. Bechterew had something similar in mind, for he mentions strong stimulation being able to tire the cell, and bring it and its dendrites to contraction.[21] The ameboid action of the dendrites possibly functioned like the positive and negative chemotaxis of leucocytes (hence, the effect of coffee, alcohol, narcotics, etc.). Cajal also held that such contractibility occurred in the glia cells which form the contact between ganglion cells, and which may thus also strengthen or check the conduction. For Cajal the contraction of the intervening glia was brought about by something generated in the ganglion cells during activity, and later extruded.‡

Subsequently, Schleich expounded a somewhat analogous theory in one of the most fascinating essays of this gifted writer.[22] Sleep is not a negation, a receding of consciousness through the presence of fatigue products in the blood—some physiological poison dimming the mind; it is, rather, an active process, a periodic reflex inhibition (stimulated through the sympathetic) of our situation consciousness, a periodic outswitching of our mental orientation in the immediate world at large, a withdrawing of all the sensory filaments with which the individual is rooted in his environment. How is it done? Between the ganglion bodies are neuroglia cells, capable through blood or lymph stream, to fill up or deplete, and so stretch out and brace connections, or draw in and sunder them. They act as moist or dry insulation plaques between the cells—easing or impeding or blocking conduction. Sleep is mind life, minus the situation consciousness — and it comes to pass through active severings in the afferent paths made possible by this ameboid activity of the neuroglia.

These highly fetching and by no means illogical* theories, based on ameboid "pseudopodia-like" activities of the dendrites of ganglion or glia cells, were somewhat punctured by the studies of Held, Dogiel, Apáthy, Bethe and Nissl, which demonstrated that the real elements of the ganglion cells were *neurofibrils* traversing the axones, and continuing through the abutting cells (*c.f.* also on "nervous gray"). I say "somewhat," for the neurofibril theory itself was later again challenged (Lenhoesék, Hoche, Schmaus-Saki, etc.)†

Let us now turn to the assumption that sleep is attained through dissociation of the cortex *en grosse*, by blocking the sensory path somewhere below and shutting out all stimuli from the periphery. This is the idea entailed in the Mauthner,[23] Trömner[24] and similar "sleep center" theories. It seems true enough that the sensorium needs stimulation to be kept awake. Reversely, dim light or darkness, quiet and repose, are so sleep-tending that they have become our veritable "handmaidens to sleep." The returning darkness of night (alternating with day), and its influence on the sympathetic system, has, in fact, often been deemed—and no doubt, for the most part, is—the cause of the periodicity of sleep. The effects of monotony and sameness have been similarly explained as a shutting down on the afferent impulses (*i.e.* monotony—*mono*tone)—thus, the zum-zum of the propeller, the

*Other endocrine theories are those of Cyon (*Pflüger's Arch*., iv., Bd. li.), who thought that the thyroid regulated the blood influx to the brain, lessened blood causing sleepiness. Lorand,[18] who cites Cyon, holds a somewhat similar idea, but is very unclear (also cf. footnote on thyropenia, below).

†It is of interest to note that outspoken or typical endocrinopathy, due to or consequent to epidemic encephalitis, is apparently of utmost rarity. Two cases of "hypophysial adipositas" following the encephalitis have been seen.[19] On the other hand, Eeman found Sargent's "white line" present (hence, adrenal insufficiency) in half of his cases (excerpts *Z. f. N. and Ps.*, xxv, 4, p. 195).

‡For other early literature on this subject see Rabl-Burckhardt's "Sind die Ganglionzellen amöboid?" *Neurol. Zent.*, 1890, No. 7, in which physiological amoiboism was first suggested; Pupin's La Neurone, Thèse de Paris, 1896; Ramón y Cajal's "Allg. Betrachtung über d. Morphol. d. Nervenzellen," *Archiv. f. Anat.*, 1896, chps. 3-4.. Duval independently of the above came upon the idea of dendritic ameboism (*Revue scientif.*, 1895, C. R. Soc. Biol.).

*I do not know why they should have been so lightly brushed aside in the literature as "overfanciful."

†Sajous (*l.c.*) ingeniously believes the neurofibrils to be *fine canals* continuous with the fibrils passing through the neuroglia cells, *containing plasma.* The neuroglia cells connect the ganglion cells with the blood vessels—are the intermediaries. Through these fine canals the adrenoxidase-laden plasma flows, the oxygen of which combines with the phosphorus of the myelin giving chemical energy, *i. e.* the nerve impulse. (Bechterew believed that one of his students, Possek, gave "convincing evidence" in his laboratory, in 1904, of a plasma-canal system within the ganglion cell, *l. c.*,[21] p. 200.)

swish-and-roll of the waves, the lulling cradle song, even the metronome or recurring pendulum swing of a clock, the very visualizing of the eversame sheep hurdling the eversame fence in the eversame way (so universally used as a home remedy for insomnia), or the mere continuous counting—all being stuff of the same thing. A famous case of Strümpell's,[25] however, seemed to confirm the point at issue, for here was an individual, with almost complete cutaneous and sensory anesthesia, in whom only the left ear and the right eye still served as avenues of sensory approach. As soon as the ear and eye were covered—wholly severing this mortal from any connection with the outer world—he slept. In fact, it took but a few moments, and sleep obtained. (A somewhat similar case had already been observed by Ziemssen.[26] Strümpell himself did not think the shutting out of sensory stimuli solved the problem. This closing down on incoming impulses, however, brought many small cortical arterioles to collapse, and so induced a depletion in the cortical blood supply (*i.e.* again the brain anemia theory). Against this theory stands the intense awakeness and awareness of Helen Keller, who neither sees nor hears, but only feels;* and, again, the fact that, when fatigued, if fatigued enough, we will sleep in spite of incoming sensations, in spite of the rattling and jaunting of the sleeping car, in spite of the repeated din of passing elevators, the noise and toots of automobiles, the whistling of locomotives —the usual fanfaron of city clamor—indeed, even through cooties itch or artillery thunder. The monotony of the aeroplane propeller, despite its terrific roar, is said to cause intense drowsiness. The cold itself, though nipping, is sleep inducing, and those near death through freezing have great difficulty keeping awake. Our dreams also prove that the wires are not all down between cortex and periphery, for many are occasioned by peripheral irritation of retina, skin, ear, teeth (pain), feelings referred from stomach, chest, or elsewhere. Thus, many if not most of our dreams are primarily peripherally (or viscerally) induced illusions.†

But to return for the moment to Mauthner's and Trömner's much-quoted and repeated conception of a blocking through something or other (irritation or inhibition of a "center," or edema or pressure, etc.) in the brain-stem or ganglion region of the cerebrum, in the chronic diseases in which abnormal processes are found in these very regions—namely, Wilson's disease, Strümpell-Westphal sclerosis and other lenticular and thalamic syndromes—*Nonne*[28] *disconcertedly reminds us that just here one finds no somnolence at all!*

Nor must we, finally, forget to mention such conditions in which the brain (cortex) is strongly invalided, as in imbecility, in the scleroses, microgyria, aplasias, etc., and the individuals are nevertheless not more sleepy or asleep than others* (in fact, some showing great mental erethism), or, again—and this is the last straw—the famous dog of Goltz (and more recently, I believe, another dog —that of Rothmann), kept alive, though both his hemispheres were removed, this dog having his periods of waking and sleeping, much as other dogs. It has also been pointed out (Ziehen) that frogs will still go into winter sleep, though their hemispheres be severed. In these cases the ganglia doubtless serve as cortex.

Bechterew (l.c. No. 2), commenting on Goltz's dog, points out that the great difference between this dog without cortex and the normal dog was the *absolute absence of initiative*. Though lower centers may take over higher activities, these now becoming automatic, such a dog does not develop initiative. Let us remember that in epidemic encephalitis an *absence of initiative* is a striking symptom—this symptom, as we might here infer, being distinctly cortical, or rather, pointing to cortical implication.

Looking over these divers sleep theories we are constrained to admit they are in no wise satisfactory, even though one finds a modicum of truth in many lines. It would seem that the various facts recorded and postulated as causes of sleep are rather accompaniments, or even resultants of the phenomenon. One is somewhat astonished that no thought has hitherto been given to the possibility of a variance between normal and pathological sleep; that is, sleep normally or abnormally induced. Let us for the moment also disregard this matter. From the evidence so far accrued, we may at least assume one can sleep whether "product-fatigued" or not, and whether there be anemia or plethora in the brain (and whether the plethora be arterial or venous). One may sleep with lowered or heightened intracranial pressure, though the latter is (pathologically) especially sleep tending. Sleep does not depend upon hypo- or hypermetabolism, though the former (in the sense of lessened energy *detonation*), no doubt, more often obtains,† and however endocrine dysfunction might induce or hinder sleep, regular sleep is nevertheless present in all types of endocrinopathy. Or one may summate these facts more graphically and conclude that in all probability sleep is not caused by, nor necessarily concomitant with fatigue-products, brain anemia or plethora, hypo- or hyper-pressure nor metabolism, nor plus or minus endocrine functioning.

Writers heretofore have likewise failed to consider the very salient point that one can sleep *on suggestion*, and be put to sleep *through hypnosis*. What is the mechanism here? On suggestion one

*Laura Bridgman was another example.

†On the other hand, it is interesting to note that a real Babinski has frequently been obtained[27] in the first few hours of sleep (when sleep is deepest), showing that there is a cerebrospinal functional break or a shunting out of some part of the cortex (the motor area?). (An interesting yet brief study of the source of dreams in this connection will be found in a pamphlet by H. Henning, Der Traum ein Associativer Kurzschluss, Wiesbaden, 1914; cf. also H. Bergson, Dreams, 1914, p. 32, and especially S. de Sanetis "I. Sogni," Tourine, 1899, Schmidt trans., 1907, chapter xii.) The maintenance of muscle tone during sleep, by the way, shows that the afferent paths are intact and that impulses are constantly streaming out.

*There is a great sleep tendency, however, in cerebral arteriosclerosis, if considerable, in late stages of paresis and in senile dementia.

†It is not improbable that various kinds of chemical activity are going on at the same time: that associated with the "up-keep" of the cell, that which has to do with the elaboration and storing of psychical energy—or the material from which the psychical energy is to come. No doubt both hypo- and hyper-activities are simultaneously present in the same cells. It is logical to presume that the feeding up and energy accumulation and storing activity is greater during sleep, the expending activity or activities greater during the waking period.

can (and the discerning physician uses the trick to advantage) produce a physiological state similar, if not identical to that during sleep: quiescence, relaxed muscles, a breathing in which inspiration is somewhat lengthened and expiration somewhat hastened, with a pause after expiration, the eyes looking somewhat upward and inward, the frontalis and eye lids being utterly relaxed. If the patient suppresses active thinking by *attending* to nothing* (this is greatly aided by the relaxed frontalis—and relaxed stapidii), and the room is quiet, he will readily fall asleep *if there are no counteracting factors.* Where such are present, these must be overcome or obviated (*i.e.* psychotherapy, etc.). Here, however, sleep is not the equivalence of this physiological status, but rather of the psychological one it creates: namely, a subsidence of consciousness, or, more exactly, a letting up on attention and association—a non-attending and non-associating—and hence, a gradual, passive waning of awareness —until its last diminuendo ebbs into the void we know as sleep.

In hypnosis the process, though differently, actively, innervated, is one which also accomplishes a retrenchment through dissociation, a narrowing of the association field, an islet of awareness being kept awake so as to maintain *rapport.* Directly the activity in this narrowed pale lets up, *i.e.* the inner attention slackens, *rapport* ceases, and the subject *falls into ordinary sleep.* In hypnosis, therefore, some portions of the cortex are awake, other portions are asleep. *Awakeness of some brain areas, then, is compatible with sleep in others.* This is very interesting to remember — and likewise the facts that both in producing sleep through suggestion and through hypnosis, the sleep phenomenon is cortical and cortically (*i.e.* psychogenically) induced.

In ordinary sleep, if one reflects for a moment, cortical areas—or islets† of consciousness—may also passingly awaken, though the individual continue to sleep. Thus, the dream, or the nightmare. Should these become *too awake,* however — their molecular oscillations too excessive—the brain as a whole awakens. In certain types of individuals (*i.e.* as in the hysterical—who are "dissociate" individuals—or in other psychopathy) the awakeness in some areas may be quite intense, and the subject still remains asleep; so, in sleep-walking, sleep-talking, *parvor-nocturnus,* etc. Ordinarily, however, though a certain small amount of psychic activity (awakeness or consciousness) may go on in the cortex, when this becomes too extensive in area or excessive in intensity, the brain as a whole awakens. Should the activity, to begin with, be too great in any area, the patient cannot fall asleep at all.

Does the area itself have anything to do with it, *topographically;* thus, are certain areas more apt to give a general alarm (diaschisis?) than others? The speech center we know is often awake (talking in sleep) while we sleep; the visual still more often (in dreams); the motor frequently, in such a way that one turns over or moves or is restless, very unusually (in the abnormal) in such a way that the individual sits up or gets up and walks about. In the latter case the eyes are open, and the patient also, though in a restricted sense, sees. Strange enough, however, as Ziehen makes mention (Phys. Psychology), movement, act and deed are usually only hallucinated in our dreams, our body lying quiet. The hearing center seems more delicate and complicated.* Where this is activated (it may take much to do so — a clap of thunder), the patient awakens. Even in our dreams visual activity predominates,† and the auditory is almost nil, though it must be admitted that sounds, possibly even minute sounds, within the ear, may awaken *auditory optic* illusions. The center of taste and smell are usually *dissociated,* though we can produce the consciousness of taste in the sleeper by putting something into his mouth, while the olfactory area, if stimulated—that is, in the event of an odor or scent reaching consciousness—more readily awakens the sleeper (odor of smoke, for instance). One might think in this discussion of the perception centers themselves, or of the "association fields," and the possibility of one or other perception center shunting (or awaking) more or less energy into the "association fields." As to the amount of activity possible in this brain area (Flechsig's), and yet compatible with sleep, one cannot at the moment tell.

Many of these questions could be approached, and possibly solved, through the study of hypnosis, if the medical profession would only forget stage hypnosis and the mysticism and pseudo-science which the word *hypnosis* connotes, and ponder the matter with the sanity and dignity it deserves.‡ At present one can only say that to maintain sleep, it seems no more than a certain amount of cortical activity, this probably varying in different individuals (either in area, or in intensity, or both), may obtain, and that if the activity exceed this amount,

*Immanuel Kant, in a little treatise (Von der Macht des Gemüts), now almost forgotten, berates the physician for his advice to the insomnic, to drive out all thoughts and *think of nothing.* Another thought will surely come in place of one crowded out. Kant himself, suffering from insomnia due to severe podagral pain, rather seized upon some indifferent thought, such as the word *Cicero,* and attended strongly upon it, and found that the pain speedily grew faint—and he would fall asleep. Attending to something indifferent, therefore, may be the better advice, though I find I can readily think of "nothing" by rapidly shifting whatever thought or picture may come before my mental eye. Sometimes moving the eyes, as if changing the point of vision, helps.

†This should not be thought of as a circumscribed area, such as a clot or an abscess might compromise, but rather as a "*circuit* of wires" ramifying in many directions.

*All sounds do not appear to affect the sleeper alike —some disturb him, some do not. He gets used to some (as, for instance, the sound of a clock or passing elevated trains), and no longer hears them. Loud snoring in the same room may not be heard, while an unaccustomed sound will prove startling. The sleeper is also strangely *selective.* A mother may be obtuse to every sound and noise, and yet awaken at the slightest cry of her infant. It is said a telegrapher might doze off and have many messages not meant for him tick by, yet be at once awakened on the sound of his key number. On the other hand, the loudest snoring does not seem to annoy the snorer!

†Most impressions from the external world come to us through the visual sense, and most persons recall their past experience in terms chiefly of residua of former visual impressions (Meumann).

‡It is interesting to note that abroad great clinicians like Oppenheim and Nonne since the war have again espoused hypnosis, the latter having therapeutically employed it to very decided advantage.

the individual awakens. This implies also that sleep *lies* in the cortex, and may be approached (induced or inhibited) through any of the avenues leading thither.

As there are two types of cells in the cortex, however, the one capable of a *psychical correlate* (*i.e.* consciousness), the other not capable of such manifestation, one cannot say whether solely the first, or also the second, plays a part in the general sleep or the general awaking. We will only remember that in the "sensory area" one *feels*, and in the "optic area" one *sees*, but that in the motor area there is no psychic correlate, and one only becomes aware of the movement after one *sees* it or *feels* the action of it. There *may* be a third type of cell. Thus, in affection of the frontal lobe we at times get neither a psychical phenomenon of sensation, nor an action without psychical phenomenon, but merely a change in *tonal feeling*. The disposition, or mood, more precisely, the tonal feeling, of such an individual may be entirely changed. In a frontal process the patient may be gravely ill, and still be in a pleasurable mood, minus all concern. The same has been seen in lethargic encephalitis. We might also remember that the remaining body cells (all, or certain areas?) play some part in sleep, the same simultaneous hypo- and hyper-metabolism activity obtaining here as in the brain cells. Cf. also the "brainless dog," above, and the winter sleep of certain animals.

And now let us round these facts into a homogenous something, which we might well term a *psycho-physical* explanation or theory of normal sleep, for our whole study leads us to this conclusion: Sleep is a sequence of phycho-physical phenomena, originally more or less consciously associated, now running off automatically, like something down a groove. It is not a simple "least resistance" groove, but rather a complex series of links or relays of conscious and reflex acts, associations and psycho-reflexes, now running off automatically, a psycho-physical series commensurate to an automatized association of acts and ideas.† Thus, at (approximately) the wonted time—night—we go to the wonted room—or a room set apart for sleep, a *bed*room—(and, though we may or may not at all be tired) start undressing, let up on mental effort (directed thinking), go to bed, lie down with muscles relaxed, the room having been darkened—and all being quiet—*close our eyes*. The scene is actively begun, but passively continued. Little by little, most of the stimuli from the peripheri, "from the environment," as Schleich would say, have been turned off and our mental *associations* for a brief spell still passively wandering, slow up—and presently come to a standstill . . . and we're asleep. One link naturally dovetails into the other. Darkness closes our eyes—it is, in fact, difficult to keep the eyes open in the dark;* and closed eyes slow up our thinking—it is difficult to think on with closed eyes—and waking is not possible (normally) without thought.

The psycho-physical series need not always run off in just this sequence. The child used to a certain cradle "starts off" to sleep as soon as it is put in. The monotony of the mother's song or rocking may start the series while on its mother's lap. The grownup may, apart from the "wonted hour" and the "wonted room," be made sleepy through *monotony*—sound of rolling waves, vibration of a train, sitting alone with no one to speak to, or nothing to read or to do, or through mere lassitude, or "spring fever"—he begins to yawn, feels his eyes grow heavy and droop—till finally they close, and sleep has come. (Does a dissociation of the "association fields," rather than merely of the perception-centers, play a prominent part in this sleep mechanism? It appears so.) *The closing of the eyes is one of the strongest links in the sleep-mechanism chain.* Above we actively closed the eyes on going to bed; here monotony has done something, *cortically*, which robs the lids of their power to hold open, and they passively droop. This inability to hold the eyes open is usually the last defeat before capitulation. Cigar smoke filling a room may irritate the eyes so that they feel heavy, and tend to close, and one gets "sleepy." In these various instances there is a cutting out of external stimuli through monotony, or closing of eyes, or both, and thus a narrowing down of cortical activity to the point where sleep supervenes. One might think of the ganglion cells (and their inter-cells) slowing up their molecular vivacity and calming down, and, because of it, many other neighboring areas kept oscillating through this ganglion activity now also becoming mute. These cells or areas would doubtless show a lessened blood content, lessened arterial pressure, lessened turgescence, lessened dissimilation (or catabolism or energy detonation) and increased assimilation.†

On the other hand, the cortex, *i.e.* the ganglion cells, *may* start the sleep process—*and here, too, begins the chapter of abnormal sleep*—by receiving an inhibiting potion, if we may conceive it so, either through the accumulation of its own fag products, or fatigue products accruing in the body and brought thither by the circulation. These so-called fatigue products need not play any part in the sleep process (as we have seen above); or they may be co-active and *help* in the cutting down of energy; or, again, they may at times prove sufficiently insistent to play a very cogent part, and so throw sand not only into the eyes (the "sandman"), but actually prove a kind of sand—or inhibiting substance—within the cortical cells, slowing up the molecular

*Not only this, but a direct jocosity or witticism (*Witzelsucht*) has been noted in both epidemic encephalitis and disease of the frontal lobes (especially frontal tumors, to which Oppenheim was first to call attention). This strange witticism has, however, also been noticed in chronic alcoholism, in senility, in the manic-depressive, the catatonic and in psychoses following brain trauma. Though the symptom points (with a question mark) to the frontal lobes, it must be admitted (Kraepelin) that it is seen in processes that go wide of the frontal area. In most of these cases the mental state also shows great instability of tonal feeling.

Connected with this frontal area appears to be still another function which may depend on *special cells* giving a particular kind of energy, namely, that accountable for spontaneity. In frontal injury or disease (especially through bullet injury) there is often found a lack of spontaneous speech, or even thinking, or spontaneity of movement or action. Cf. Schob's recent study, *Allgemein. Zeit. f. Psych.*, No. 77, H. 4 and 5 (cf. also on *initiative*, above).

†For a detailed account of acts and ideas in series become automatized, and a mingling of conscious and automatized series, see our study on Feeling, Association, and Psychoreflex.[2]

*Conversely, it may be hard to keep them closed in the light. Thus, Nonne mentioned the difficulty he had falling asleep in the North with the unwonted midnight sun streaming through the windows.

†Just what part the thyroid would be playing one can scarcely conjecture, not knowing whether its activity is primary and intracellular as a ferment or specialized food, or secondary, its action being on the cerebral blood influx (as Cyon thought), or on the blood pressure, or as an oxygen carrier or detoxicating antibody. Clinical experience would lead one to intimate that thyroid substance acts as a *sensitizer* to the cortical cells (heightening reception to stimuli and expediting detonation, or in some way intensifying tonal feeling?). *Thyropenia* would therefore not cause, but rather aid sleep through cortical desensitization—just as, reversely, thyroid feeding (therapeutically) stimulates alertness and mental acuity.

speed (or drawing in of dendrites, if you will). In this way it comes about that *energy* is not handed on, the nerve *charge* not being propulsive enough, not *going through.* Hence, the associations show breaks—and, finally, no longer *connect.*

We can feel it coming on—and in a measure strive to ward it off. Indeed, the fatigue products, whatever their nature, or rather their activity, may be combatted. Thus, however fatigue-products burdened we may be, if a book is *interesting* enough, we tirelessly read on. The *need* of completing a task may keep us at it long past the usual sleeping hour. Desire for enjoyment (the dance, the card game) may make us quite immune to "products!" They are also neutralized by morphine (in fact, remarkably so), by caffeine and nicotine in the form of coffee and cigarettes, and stimulants like a splash of cold water or cold tub, or by keeping in motion—and finally are put to actual rout by worry, care, fear, eroticism and pain.*

But the "fatigue products" may be reinforced or substituted by "products" in the nature of chemicals, which may be mild, like lupuline, hops and alcohol, or stronger, as in the case of sleeping drugs, or still stronger, in the form of narcotics. These all do something in the cortex inhibiting ganglionic catabolism, inducing sleep. Or, again, with overdosage, they stir rather than sooth, and so lead to delirium and manic or other psychotic outbreaks. Still other chemicals, bio-chemicals, belong to the same category, namely, autointoxicants, as found in uremia and eclampsia, and toxins of infections, products of bacterial activity and possibly bacterial decay. These, too, benumb the sensorium into sopor or lethargy, and, if sufficiently ample or intense, lead now to delirum, now to coma, now to jactitation, and again to paralysis or death.

Pathological sleep, or sleep pathologically induced, therefore, resembles only that type of normal sleep which begins with cortical de-energization. It merely resembles it, however, and is not identical, for normal sleep, to a considerable measure, can be held up, and is outbalanceable through interest, need, etc., and is soon nullified through rest; while pathological sleep, sleep that is drug- or toxin-induced, is aggressive and insistent, scarcely, if at all, combatable (unless one remove the cause), and not annulled through rest.

Our theory may claim validity, even though we do not precisely know what goes on in the cortex. The ganglion or cortical *activity* achieving and sustaining consciousness is but one of several activities going on in these cells. We might conceive of it as a special dissimilative process in which *energy* is produced and sublimated, or that during rest periods potentially amassed, now tensely set off. We say *special* process, for we know that other energies, such as electricity, warmth, that which maintains nutrition and life of the cell, etc., are also being elaborated in the cells. In psycho-physical theories, such as Ostwald's or Lehmann's, physical activity is presumed, through a dissimilation process, to be transformed into psychical energy. In the waking state this is constantly going on. As we are "keyed up," it increases. Some of it is also going on during dreams. Recently Berger[30] concluded that in brain work an energy amount of about twenty meter-milogram is transmuted into psychical energy per minute. When this special dissimilation simmers down (a slowing of the intramolecular velocity, a letting up on electronic cleavage?), it is probable that at the threshold a state sets in, which, if widespread in the cortex, gives the phenomenon of sleep. It may be that, through lessened activity, the dendrites are drawn in, breaking connections, or that, in some way, the lessened ganglion activity gives the neuroglia the overhand, and this clinching in shuts off conduction; or, finally, as Cajal and Schleich thought, in the process, something which stimulates the glia may be extruded from the ganglion cells.

When we come to the pathological, another element is added, that of aberrence of the process. The simmering down may be so rapid or go so far that it takes a long time to again establish normal reactivation (hence, the cloudy, thick head after a narcotic). Or, on the other hand, the dissimilation process may become so intense — *or abnormal* — that we get not merely awakeness, but elation, delirium, etc.

There are individuals, who are in themselves abnormal, who are over-sensitive or *idiosyncratic.* Overexertion or fatigue unmans them, and it takes several days before they recover; or, again, such overexertion or excitement produces an insomnia lasting for several nights. Again, drugs, even mild hypnotics, may be reacted to abnormally. Bromide, one of the mildest of cortical depressants, and most easly borne, will muddle some individuals to a remarkable degree. A patient of mine, after a dose or two, came down with a confusional psychosis. Shortly after, not knowing that bromide had been responsible, she again partook of the drug, and went through a similar attack. Luminal is another mild and harmless sedative, acting, like bromide, on the cortex. I have had an epileptic boy on this drug for three years, taking daily doses without the slightest ill effect. Another patient, however, recently, after a few small doses, developed a temporary confusional state. Some time ago I saw a case with Dr. B., the patient being in a remarkably elated, euphoric state, experiencing no fatigue (subjectively) and seeming to need little sleep. The acuity of all his senses was increased, subjectively immensely so. It developed that this patient was intoxicated with chlorotone, which he had been using over a long period. Finally, though chloroform narcosis is for the most part innoctious, I have been treating a patient who, after such narcosis, developed a mental depression and derangement which has persisted and, after several months, has not yet cleared up.

A few other *cortical-sleep* incidents may with interest be added: Fatigue weakens volition. This makes psychasthenia especially pronounced on fatigue. The epileptic, after a convulsion (cortical upheaval and exhaustion), falls into deep sleep. A dipsomanic attack, in which the individual may wander and remain awake throughout a whole night or two, ends in a long sleep. The patient with *flight of thought* cannot sleep (though there must be a tremendous over-activity in his cortex, the same being true in mania, a patient being able to toss about and scream and talk throughout days and nights without the least respite). In alcoholism the cortex is excited; after the debauch, deep sleep supersedes. In chronic alcoholism you may get delirium tremens or a Korsakoff psychosis, both being cortical affections.

(Scanning the above paragraphs dealing with the pathological, especially in considering *delirium,* but also in thought of elation and depression, the theory of amœboid dendrite activity does not seem quite *sufficient.* Here intracellular chemical changes—abnormal combinations or cleavages, together with abnormally slow or rapid or excessive energy accumulations and detonation—seem to give more rational explanation.)

In our careful examination of this subject we have come upon no facts leading to the assumption of a sleep-center in the brain-stem, or a sleep-center elsewhere in the cerebrum. Indeed, our data aggregate in but one inference, and that, namely, that normal sleep is a *psychophysical* phenomenon, wholly referable to the cortex, the *deenergization* of

*Strange to say, in *neurasthenia,* which is a state of chronic nerve fatigue (central-nervous system fatigue), the individual is most fatigued (both actually and subjectively) in the morning after a night's sleep, and "wakes up" more and more as the day draws by, to be widest awake and without fatigue by night.

the (presumably) ganglion cells, either through "products," or suggestion, or habitual psychophysical sequence, or diminished stimulation, being accountable, or, again, a *dissociation of areas* (and hence, of activity and *energy*) through suggestion or the *habitual* nightly reflex sequence. In pathological sleep the cortex itself—the ganglion cells—is *de-*, or better still, *dysenergized*, by deleterious substances (toxins, etc.) working directly upon the cells, blanketing, as it were, their molecular oscillatory play.

The clinicopathological study of encephalitis, and especially *epidemic* encephalitis, tends to strengthen rather than weaken our conclusions. It will be found that, in the light of more modern researches, Mauthner based his theory on false premises, for we now deem many of the symptoms of Wernicke's poliencephalitis superior due to the cortical involvement of that disease, while the African sleeping sickness has also since been found not of brain-stem causation, as Mauthner believed, but a cerebral disease pathologically very similar to paresis and with decided cortical effects.[31] Hysterical narcolepsy, the third instance of Mauthner's evidence, we now hold entirely cortical and hence of no evidential value whatever. In epidemic encephalitis we come upon cases (they will be cited in a forthcoming publication) in which there is decided somnolence *without* involvement of the superior brain stem area, and again cases in which, despite the brain stem involvement, no somnolence obtains. Indeed, we shall endeavor in our chapters on *chorea*, *myoclonus*, and *cortical* forms of the disease, to show that it is far more cortical, in spite of the general absence of cortical necropsy findings, than has hitherto been thought. Finally, and this is most important, Wilbrand and Saenger, in their work on The Neurology of the Eye,[32] point point out that the falling of the lids in sleep has nothing to do with the oculomotor nuclei, but must be a *supranuclear* phenomenon. If the seat of the sleep-inducing process were the region of the oculomotor nuclei, they contend there is no reason why the other muscles innervated from this region should not also be paralyzed. Yet this is not the case, for the bulbs do not assume the position they attain in complete nuclear or asthenic paralysis, but turn upward and inward and also show movements. The contracted pupils (they are contracted in sleep) denote not paresis, but increased tonus of the sphincter iridis, a fact likewise not compatible with a close-down of the nuclei of this region. For Wilbrand and Saenger the cortical center of the levator is probably in the parietal lobe and the ptosis in sleep due to the dissociation of this center in the general dissociation of the cortex. Curiously enough, this study of Wilbrand and Saenger has been entirely overlooked.

From the viewpoints of physiology, psychology, and pathology, then, our theses are sustained if not confirmed, and nowhere are data forthcoming which really negate them. That much as yet remains unclear, unanswered, is true enough, but this does not impair our inference: There is no sleep center; nor is sleep occasioned through subcortical block. Sleep is a psychophysical sequence—a cortical manifestation. In epidemic encephalitis it presumably is likewise cortically induced.

60 WEST EIGHTY-FIFTH STREET.

Some Cancer Statistics from a General Hospital.—During the period 1901-6 inclusive there were admitted to the Hôpital Tenon, Paris, 1,501 cases of cancer. Of these patients 766 died in the hospital, while 735 left the institution alive. None of the latter was followed up, but it is not believed that a single one survived for any considerable length of time. Of the total, 518 were men and 983 women. In regard to locality 409 cases were cancer of the uterus, 296 of the stomach and 153 of the breast. Cancer of the digestive tube as a whole was much more common in men—364 to 247 in women. Above the diaphragm in the alimentary canal ten men were affected with cancer to one woman; below the diaphragm cancer in men predominated to a considerable extent. The average age of women entering hospital for treatment of cancer of the breast was fifty-four.—*Le Progrès Médical.*

ACTINOMYCOSIS.

WITH REPORT OF A CASE.

By EDGAR A. VANDER VEER, M.D.,
ATTENDING SURGEON, ALBANY HOSPITAL, AND
ARTHUR M. DICKINSON, M.D.,
ALBANY, N. Y.
ASSISTANT ATTENDING SURGEON, ALBANY HOSPITAL.

ACTINOMYCOSIS is a more or less chronic infective process occurring in cattle and less frequently in man. The lesions produced in animals lead to the names of lumpy jaw and wooden tongue.

The peculiar clumps produced by the organism in this disease were first noted by Von Langenbeck in 1845. Bollinger discovered the organism in material obtained from an ox in 1877, and Israel reported the first human case in 1878. However, it is probable that previous writers described cases of a similar nature but considered the tumors to be osteosarcomata. Harz was the first to give the causal agent the name of actinomyces or ray fungus.

The actinomyces are organisms of the group of trichomyces which possess many characteristics relating them to the true molds or hypomyces. The trichomyces are distinguished from the higher fungi by their slender filaments and more simple life history. Of the group of trichomyces the actinomyces are the most important and best known.

The parasites appear in the pus from lesions as small granular bodies visible to the naked eye and having a yellow or grayish cast more or less similar to sulphur bodies.

As seen under the microscope these granules appear as rosette like masses having an opaque center which consists of closely meshed networks of filaments. These filaments show true branching which helps to distinguish actinomyces from others of the trichomyces group. Around the margins are seen the characteristic striations, some of which end in club shaped bodies. The organism as found in animals usually exhibits these club shaped bodies, while that found in man usually does not. The appearance of the club shaped bodies is generally interpreted to mean that considerable resistance to the growth of the organism has been present. In addition there occur coccus like bodies in and about the filaments, but their significance has not yet been decided. The organisms are Gram positive but decolorize with 95 per cent. alcohol. According to Wright they are anerobic, but other bacteriologists place them in the aerobic class. They do not form true spores.

As a rule the infection takes place through the upper alimentary tract. In man the teeth and tonsils are regarded as possible portals of entry. The disease occurs endemically in cattle but is rarely communicated from one animal to another. There is no report of the disease being directly transmitted from animal to man. One author reports cases occurring in man which he believes to have been due to the fact that the men slept on hay and straw. As the disease is usually found in men who are closely associated with hay and straw, and particles of these are sometimes found in the lesions, it has been suggested that hay, straw, or other types of grain may play an important rôle either by actually transferring the infection or by causing an abrasion of the tissues and allowing the entrance of the infective organism. The portals of entrance of the actinomyces in order of importance are (1) mouth, teeth, and tonsils; (2) respiratory tract; (3) gastrointestinal tract; (4) skin.

From the above it can be seen that actinomycosis may attack many parts of the body, although it is most commonly seen in the region of the angle of the jaw. It is said that in 56 per cent. of all reported cases of actinomycosis, the lesion has been in the jaw region; the digestive tract has been invaded in 20 per cent. of cases, the lungs in 15 per cent., and the skin in 2 per cent. The remaining 7 per cent. of cases involved the breasts, ovaries, testicles, bones, brain, etc.

Generally in man the infection is a localized process, spreading only along the tissue planes by continuity. Rarely do we get a generalized infection due to metastases. Late in the disease blood vessels may be ulcerated into and thus infective emboli are carried to some part of the body far distant from the original focus, and these emboli cause independent lesions. In the spread of actinomycosis the lymphatics play but a slight, if any, part. No glandular enlargements develop near an actinomycotic lesion.

The symptoms of the cervicofacial type of actinomycosis fall into two stages: first, the stage of induration, and secondly, the stage of softening. In two to four weeks after infection takes place there develops about the site a painful swelling. It is firm in consistency and symmetrical in outline. As the swelling increases, trismus of the jaw develops. As a rule, in the primary stages there is little systemic reaction, such as fever, etc. Indeed, the swelling is often thought to be due to carious teeth, mumps, or osteosarcoma. Then we pass on to the stage of softening in which there is usually secondary infection. This appears in six to eight weeks. The mass breaks down and sinuses form. The pain to a large extent ceases and the patient is able to open his jaws sufficiently to eat and talk. The sinuses may persist for months, alternately opening and closing till finally a great thickened jaw and cheek remain showing many scars. The bones are rarely affected in these cases.

The prognosis is not very good. In infections of the face and neck the mortality is 11 per cent.; in infections of the thorax, 83 per cent.; in abdominal infections, 71 per cent., and in cases where the brain is involved, 100 per cent. At the best the disease is one of a very chronic nature and prone to exhaust the patience of both the physician and the victim.

The treatment does not appear to he very satisfactory. Abroad, and to a less extent in this country, potassium iodide has been used; also methylene blue and copper sulphate. As *x*-ray and lately radium have both been tried in the treatment of most diseases, so they have made their appearance in the treatment of actinomycosis. Some rather good results have been claimed as a result of *x*-ray treatment especially by English writers, while physicians from the Continent are equally enthusiastic over the value of radium. Probably the secret of the cure, if such we may call it, lies in the effects of time and kindness of nature, aided by local and systemic treatment of any of the above methods.

Case Report.—E. S., male, age 58, born in the United States, white, farmer by occupation. Admitted to the Albany Hospital January 11, 1921, for the relief of pain and swelling on the right side of the face.

Previous history, essentially negative.

Present condition began four weeks ago as a small, but painful, "boil" located in front of the right ear. This was painted with tincture of iodine by the patient, but such treatment did not improve it. The "boil" gradually increased in size and extended till it made opening of the jaw almost impossible. Pain was terrific until one week ago, when it became less severe. For the past three weeks the patient has been unable to masticate any food at all.

Last fall the patient assisted in the threshing of grain and frequently kept a piece of hay, grass, or straw in his mouth. To the best of his knowledge he had no bad teeth or breaks in the buccal mucosa.

On admission the patient's temperature was 101°, pulse 84, respirations 24. The blood pressure was 124 systolic and 82 diastolic.

The appearance of the patient was very striking. The whole right side of his face was markedly swollen so that vision from the right eye was impossible. The jaws could be opened scarcely enough to admit the ordinary lead pencil. The right eyelids were heavy with edema, and on separating them there was observed a very marked injection of the conjunctiva. A purulent discharge ran from the corner of the eye. The brawny infiltration of the facial tissues was dusky red in color, leathery to the touch, and did not pit on pressure. There seemed to be several soft areas where necrosis had taken place. There were no palpable lymphatic glands in the region affected or elsewhere in the body. The physical examination as concerned the rest of the body was essentially negative. The white blood count was 16,000. The Wassermann reaction was negative. An examination of the urine disclosed a very positive albuminuria with the presence of many granular casts. Otherwise it was negative. An *x*-ray examination of the area involved showed absence of any involvement of the bony structures, the examination therefore ruling out osteomyelitis.

The immediate treatment consisted in the application of large hot packs at frequent intervals, with the administration of large quantities of fluids and relieving the colon by a mild cathartic.

The next day, under procain anesthesia, multiple deep incisions were made into the mass and small rubber drainage tubes were inserted. Specimens of the material obtained upon incision were immediately submitted to the laboratory for examination.

Upon the patient's return to his room hot packing was again instituted and continued throughout most of his stay in the hospital. He was given two intravenous injections of arsaphenamine, each dose being 0.4 gram at five day intervals.

The laboratory reported as follows: "The pus contains sulphur granules which, when crushed, show typical mycelial threads. Cultures of the pus show growth which resembles actinomycosis."

During the patient's stay in the hospital his eye was examined and treatment instituted by an ophthalmic surgeon to preclude the possibility of his having an extension of the process to the conjunctiva. The swelling of his face gradually decreased so that he could see quite well from the eye even on the affected side, and, for the first time in six weeks, he was able to masticate his food. He was discharged from the hospital on January 29 as improved.

Following his discharge from the hospital everything went along smoothly for about six weeks when the swelling reappeared and broke down again. It discharged for several weeks and then healed up. Since then he has had no further trouble.

The patient was last seen on August 2, 1921, at which time everything was extremely satisfactory, and except for several scars upon the side of his face and some slight thickening of the facial tissues, the appearance of his face was normal. As some eight months have expired since the infection cleared up, I believe we can consider this case as cured.

COMPLICATIONS AND SEQUELÆ OF INFLUENZA PNEUMONIA.*

By ORRIN S. WIGHTMAN, B.A., M.D.

NEW YORK

Before considering the complications and sequelæ of influenza pneumonia, it might be wise to define clearly what is generally understood by pneumonia. The classical text book picture of pneumonia distinguishes two general classifications: (1) lobar pneumonia, and (2) bronchopneumonia. The former followed exposure, was accompanied by severe chill, pain in the side, rise in temperature, cough, flushed face, with delirium and continued high temperature, terminating by crisis usually from the eighth to the eleventh day. The pneumococcus was credited with causing the disease.

Bronchopneumonia was a diffuse type of the disease, involving small areas and found oftenest in children. The influenza of a decade ago appeared under the name of la grippe; it was ushered in with an acute coryza, moderately high temperature, bone and body ache, and assumed one of a number of types. The nasal type with symptoms in the nose and adnexa, the abdominal type with intestinal symptoms predominating, etc. It is hardly necessary to mention the various forms of influenza as they are sufficiently recent to be familiar to every physician here.

I mention briefly pneumonia, bronchopneumonia, and influenza, so that we may clearly distinguish between these and the late epidemic of influenza pneumonia.

A more correct definition of influenza pneumonia might be "an acute massive infection of the lung." When we use the term infection we naturally become liable for both the term "infection" and also the type of invading organism, and it is in this very particular that influenza pneumonia is separate and distinct.

Every epidemic of a dominant or new character is virulent only as long as the human host is unable to cope with it. But just as soon as man provides his own protective agency, usually by desensitization, and the fact that by successive subcultures from man to man the invading organism eventually loses its virulence, just so soon the disease ceases to be a menace to the human race.

The history of the world has repeatedly shown that large gatherings of people are invariably followed by a rapid spread of some dread disease. The carriers quickly disseminating the fresh cultures on their return to the homeland. In the recent World War, the soldiery was rapidly invaded with influenza, and the economic problem of looking after them enabled the medical profession to obtain accurate data which could have been secured in no other way. Hundreds of thousands were thus tabulated and the careful studies made give us unquestioned facts upon which we can rely.

Thus we learned that the pneumonitis was dependent for its severity upon the type of invading organism. Lucke, Wight, and Kime at Camps Zachary Taylor and Knox, after a careful study of 126 necropsies with routine cultures, found that in

*Read before the Polyclinical Society at its May meeting, 1921.

the earlier part of the epidemic the influenza bacillus was most often found. As the epidemic lengthened, secondary invaders appeared, with anatomical complications peculiar to the new organism. These were the non-hemolytic streptococcus and the pneumococcus. When more than one organism was present the disease was more virulent. Lyon confirms this at the Walter Reed General, and states that the secondary organisms are the ones which chance to be in the nasopharynx at the time of infection.

In our civilian practice *Streptococcus viridans* and *S. hemolyticus*, together with the influenza bacillus and the pneumococcus were the greatest offenders. Instead of identifying the form of pneumonia by Types I, II, III, and IV, it seems far simpler to me to use the name of the invading organism. The type method is generally used, but I fear the medical profession is using a Rockefeller trade-mark instead of a universal classification.

We are prone to consider influenza pneumonia as distinctly a disease of the lungs. This is not so. While the spectacular results are found there, we must not forget that although the hemorrhagic brunt is borne by the lungs, still hyperemia and hemorrhage are strikingly found in the brain, ears, liver, spleen, and meninges with rapid degenerative changes in the suprarenals, necrosis in the lungs, and focal infections in the head, chest, liver, and other organs.

The blood picture shows an intensity of invasion alarming in character, with a relatively poor response in polymorphonuclear leucocytes. There is a stimulation of lymphoid tissue and a myeloid intoxication.

At the Walter Reed General, Lyon[2] found in a series of fifty-six necropsies with a duration of life of 12.4 days an average leucocyte count of 5,537 with extremes of 2,675 and 11,900. Among these cases 20 per cent. showed no real pneumonic process except the classical hemorrhagic pneumonitis; Lyons also mentions findings I wish to emphasize later—namely, bronchial lymphadenitis.

The complication of early moment to the physician is that of suprarenal involvement. A question has been raised as to whether the lowered blood pressure is due to the dysfunction of the adrenals or to the toxic effect of the disease upon the heart muscle itself.

Weiss[3] discusses in a very interesting way the toxicity of pneumonic exudates; he claims there are two toxic proteins: (1) a sensitization protein, identical with pneumotoxin, and (2) a pyogenic albumose. The globulin fraction is nontoxic, but the albumin fraction is toxic, due to the digestive action of the enzymes of the exudate.

It is only when antibodies are in excessive amounts that the deleterious influences of the toxins and albumoses are neutralized. The equilibrium of mass action thus changes from febrile toxemia to to the nonfebrile, nontoxic state. This change is an abrupt one and is generally known as crisis.

We have all observed the very marked lowering in blood pressure—the systolic pressure in my own cases running from 90 to 100 mm. Cowie and Beaven[4] at Ann Arbor in a series of cases reported slightly higher than this, viz., 99 to 115 mm. They maintain that in acute infections the toxins produced call for endocrine products to combine with them in a neutralization process; that the lowered blood pressure in influenza pneumonia is endocrinal rather than cardiac.

In addition to the blood pressure, we know that the blood sugar is promptly increased by any interference with the suprarenal function. Their experiments proved to their own satisfaction that while the injection of ten to fifteen mm. of epinephrin by the intramuscular method every four hours, or four times during the day, produced a reaction causing palpitation, headache, and nervousness, with lassitude and twitching, still the benefit in increased blood pressure was questionable when compared with the above symptoms, and the epinephrin was discontinued. They conclude that the proper method of administration has not yet been found.

This leads us to a general observation relative to endocrines: It is much easier in endocrinology to build up an interchange of correlating symptoms among the various glands and convincingly prove the dysfunction of a particular gland or glands, but with the modern methods of administration it is quite another thing to repair or compensate that dysfunction by oral glandular administration.

Mackenzie's conclusions as to the effect of influenze upon the heart are summarized under three headings: (1) the effect due to the rise in temperature, (2) the effect of the toxins produced, and (3) the direct invasion of the heart. Inasmuch as the toxins are limited to their production and neutralization, the heart has only to sustain this burden for a short period, viz., ten to fourteen days. The invasion of heart muscle produces cardiac irregularities with both tachycardia and bradycardia, but Mackenzie himself expresses surprise that hearts severely infected so thoroughly recover with no bad after effects. He thinks the heart suffers more from the indirect insult to the central nervous system. This would seem to be borne out by the surprisingly few cases referred to us for postinfluenzal heart conditions.

Another question which has frequently confronted the medical profession is, What is the effect of an attack of influenza upon the tuberculous subject? More interest still centers upon the effect upon the pretuberculous type whose latent possibilities are always a source of worry to the family physician.

Many of these cases showed early and positive mediastinal involvement. Our civilian work dealt largely with the *Streptococcus viridans*, and this particular organism seemed to have a predilection for peribronchial tissue and glands. These were the cases which on physical examination showed apparently unresolved areas posteriorly at the roots of the lungs. The voice sounds were pronounced here and out of all proportion to the general condition of the patient. This physical picture continued for weeks after the patients had recovered and seemed in the usual health. They did not complain of the lungs, but rather of a lack of "pep" and early fatigue.

It is interesting in this connection to note the report of Stivelman[5] of the Montefiore Country Home Sanitorium at Bedford Hills—his conclusions being as follows: Tuberculous and nontuberculous

subjects seem to have been equally affected, and were susceptible alike, the percentage in each case being 24 per cent. Early and advanced cases were equally affected. Pneumonic consolidation occurred as frequently in the nontuberculous as in the tuberculous. The mortality was 11.4 per cent. Careful observation for four months and reexamination showed but two patients who were the worse for the experience.

The points which I wish to emphasize particularly in this paper are that influenza pneumonia is a massive toxic invasion of short duration—leaving relatively few scars of a permanent character upon those who recover, in proportion to the severity of the invasion.

That we should be careful in our prognosis in the post influenzal stage when the physical signs and the *x*-ray pictures of the chest may suggest symptoms of consolidation. These are in reality often mediastinal glands, and we should not commit ourselves to any diagnosis of tuberculosis until time and a careful observation have justified a more serious conclusion.

CANCER DEATH RATE IN NEW YORK CITY DURING 1921.

By L. DUNCAN BULKLEY, A.M., M.D.,

NEW YORK

SENIOR PHYSICIAN TO THE NEW YORK SKIN AND CANCER HOSPITAL; MEMBER OF THE AMERICAN ASSOCIATION FOR CANCER RESEARCH, ETC.

The continued and ever-increasing and alarming rise in the death rate from cancer in New York City should attract the serious attention of the medical profession, that it may seek the reason for it and endeavor to overcome the difficulty, as would be the case with any other malady. Simply to urge greater vigor and more diligent laboratory research on rats, mice, and guineapigs, and to inspire a more active employment of surgery, *x*-ray, and radium, seem only to raise the death rate from cancer. Sir James Paget once said, "Assuming that the patient survives the risks and the effects of the operation, I venture to say that the number of cases in which the disease does not return is not more than one in five hundred." Is it not time for all of us to consider whether our conception of the nature and treatment of cancer is correct or not?

Another year has fulfilled the predictions of former studies,* that at the present rate of increase the deaths from cancer would, in some years, exceed those from tuberculosis; but no one could imagine that this would occur so soon as it has, nor that the excess of the deaths from the former over the latter disease, would be so very great, as it has been during the year just passed.

According to the Weekly Bulletins of the New York City Board of Health the total recorded deaths from cancer in 1921 were 5656 (males 2534, females 3122) against 5361 the preceeding year, an increase of 295 or a little over five and one-half per cent., whereas the yearly increase throughout the United States has never been over two to three per cent., sometimes much less. The total mortality from all causes in New York City, during the last year, as compared to that of the preceding year, fell twelve per cent., against an increase of five and one-half per cent, from cancer, and a fall of sixteen and six-tenths per cent, in the death rate from tuberculosis.

Those who have tried to argue against the demonstrated increase in the mortality from cancer have always claimed that it was not actual, but that the error arose from: (1) Increasing population, (2) increasing average longevity, into the cancer age, and (3) improved diagnosis and more careful death certification. Figures show the unreasonableness of all these. Thus, the population of New York City has not increased five and one-half per cent. since last year, also the general death rate and that from tuberculosis have fallen greatly, and the longevity of life extending to the cancer age has certainly not increased five and one-half per cent. in the year. Nor, thirdly, could the diagnosis of cancer have improved so greatly in the year; while I have been repeatedly told by undertakers that the figures given by the Board of Health are certainly far too low, as they personally know of many instances of death from cancer in which the name of the disease was withheld for family or other reasons.

The average weekly number of cancer deaths was 108.6 persons, or 15.5 per day, and the greatest number in a single week was in that ending Oct. 29, namely 130, or 18.5 a day; the lowest number in any one week was 88, or about 12.5 persons a day. There were only 15 weeks in which there were less than 100 deaths from cancer.

This outlook is more discouraging when we compare it with the death rate of tuberculosis during the last year. Against the 5656 deaths from cancer, there were only 5225 deaths from tuberculosis, or an excess of 431 from cancer; while, as already stated, the tuberculosis death rate has fallen 16.6 per cent.

In the United States Registration area, as is learned from a special report from Washington, the deaths from cancer had risen in the year 1920 from 80.5 to 83.4 persons per 100,000. The rise in the cancer death rate is all the more startling when we examine the Special Cancer Report issued by the United States in 1914, which shows that the population from 1900, in the enlarged registration area, had a little more than doubled, whereas the number of cancer deaths had almost tripled in the same time.

Tuberculosis was felt a while ago really to threaten the existence of nations, but with well directed medical care the mortality has fallen steadily 43 per cent., and it is no longer the terror it once was, to those who can secure proper treatment. Syphilis was once called the great black plague, and a few hundred years ago, swept, mainly by extragenital infection, through whole villages in Europe; but now is well under control by properly regulated medical treatment.

*See Medical Record, March 2, 1918; January 18, 1919; March 20, 1920; January 29, 1921.

But cancer, the great red plague, seems to be still pursuing its mad career, and carrying off 80,000 persons in the United States each year (consequently with 80,000 new cases), with an acknowledged mortality of about 90 per cent. of those once affected; and many are asking how its steady advance can be averted and its prevalence diminished. The idea or theory of the local nature of the lesions called cancer has been shown to be untenable, and the evidences are steadily increasing of a systemic or constitutional nature of carcinosis, of which the local lesions, commonly called cancer, are only the local manifestations or products, as are the late lesions of tuberculosis, syphilis, arteriosclerosis, rachitis, apoplexy, etc. Is it not high time for the general medical profession to try, at least, what the careful intelligent and prolonged application of medical acumen can accomplish on a large scale, to diminish the incidence and mortality of cancer, from which it is estimated that there are 300,000 sufferers in the United States to-day?

A CASE OF SEPTICOPYEMIA WITH RECOVERY.

By G. W. STONE, M.D.,

NEW YORK.

FORMERLY HOUSE PHYSICIAN, KNICKERBOCKER HOSPITAL.

During a portion of the writer's hospital service he had charge of a case of puerperal septicopyemia and he keenly felt his responsibility. Neither was the burden that he bore lightened by the discovery that a single agar blood-test plate revealed twenty-six colonies of active *Streptococcus hemolyticus;* nor was it any present help in time of trouble when, in consequence of that showing, the visiting attendants in their wisdom simply quit, surrendered hope, abandoned effort, and unanimously predicted a fatal issue. In which course they were sustained by the authors of former days who considered the condition "almost invariably fatal." The authorities of to-day admit that "mild cases, if very mild, sometimes, though rarely, recover."

All of which leads one to believe that when a medical man is shown the conclusive evidences of an acute bacteriemia with a couple of dozen of colonies of *Streptococcus hemolyticus* on each plate, then that man becomes eloquently emphatic upon the simple text that "nothing can be done for the patient." In other words, the dread of puerperal septicopyemia is so great that the mere exhibition of adverse showings upon a Petri dish suffices to paralyze a physician's every thought-effort at resistance, in advance of the initiation of any combative impulse that might otherwise be directed against the disease. At any rate, in this particular instance, the outcome of the writers' appeals for help among the members of the visiting staff was an instruction that the case was to be made a special one and was to be put in the care of Dr. Douglas H. Stewart, to whom one was to look for advice and counsel while making what was considered to be either a perfectly futile sort of fight, or an idle attempt to save a doomed patient. One of the Doctor's first orders was that the world of bactericides and the wealth of germicides were to be forgotten and that the employment of Catalyzers and catalysis was to be carefully studied. Because, while it might appear to be both natural and rational to suppose that some bactericide would prove available in arresting a bacteriemia, yet clinical and laboratory experience united in demonstrating this supposition to be a fallacy, when the actual conditions within the blood-vessels were taken into account.

There are eighteen cases scattered through the literature in which a complete recovery was brought about. In all a dependence was made upon a catalyzer, and the two catalyzers that were at hand were colloid silver and bicarbonate of sodium. These have been used intravenously; but this patient was altogether too ill to withstand the severe reaction that follows that method. The framework, upon which the treatment soon to be described was hung, was derived from Wolf's article in the *Medizinische Wochenschrift,* 1913, No. 20, page 944, and from Vorschütz' brochure in the *Zentralblatt für Chirurgie,* 1912, No. 50, page 1719. These treat of silver and sodium respectively. The action of these preparations is due to their powers of stimulating leucocytosis and to their catalytic properties, so that while there may be little or no direct influence upon the blood-borne bacteria, yet an efficient action is indirectly induced through a hyperleucocytosis, which is easily demonstrated under the microscope. At the same time noxious

bacterial products are detoxified, eliminated, and altogether catalyzed. In the case under consideration the bacteria would disappear; but they would return, though always in smaller numbers, so that it was very evident that they were working in an environment that the treatment was rendering distinctly unfavorable.

The amount of space necessary to set forth the temperature, pulse, and respiration chart would be great and perhaps no useful end would be served, because the whole matter might be summarized in the advice to the reader, when in a similar difficulty, to neglect the chart and to get a pathologist to count the colonies of bacteria that show on the Petri dish. Then, as it was in the case herein reported, if twenty-six colonies become fourteen and nine and none, even though a further test reveal nine colonies by way of return, favorable progress may be foretold, even before the chart manifests any evidence in the matter. For the chart will manifest a disturbance until both bacteria and toxins are eliminated. A schematic figure, that occurs and recurs when things are going well for a septicopyemia patient, and when the fight is being carried into the invader's territory by a powerful catalytic agent that is producing an environment against which the bacteria can no more act, but become any army deprived of ammunition and supplies, is this:—Suppose the maximum temperature be 105°, the minimum 99°, with the maximum pulse

130 and its minimum 100. The respirations may be anything from 24 to 34.

At figures 1-2 the blood shows a leucocytosis and the silver-soda injection is given. At 3 it will be found that the cell wall of the leucocytes has been destroyed, that there is a leucopenia, but the antitoxin contents of those ex-leucocytes have been dumped into the blood-stream, therefore the chart looks *worse*, the patient looks *better*, and the colonies of bacteria are few or absent. At 4 there is a leucocytosis again, and at 5 the stimulated overproduction of leucocytes produces a hyperleucocytosis. Again and again did it occur in this case that some interested or curious physician would look at the chart, shake his head sadly and then would look at the patient, with the result that words to the effect that the patient "looked so very good," were almost forced from him by the difference between what he did see and what the chart had led him to think that he was going to see. One gentleman remarked, "If this woman is as sick as the chart says she is, she ought to have holes under her eyes." She did not have those "holes" two days after the treatment was established, though the shadows had been quite dark enough before that treatment was begun. In short, after the treatment was well under way, the patient promptly ceased to look sick, while the chart started off on a series akin to the schematic figure. The patient might have been out of bed days before she was, if Dr. Stewart had not insisted that patients of the sort had lost their lives through a masked endocarditis. Therefore his orders were to keep the patient recumbent, though she was allowed to roll from side to side. A diagnostician was called from the medical side of the hospital and after careful examination and tests (blood-pressure, etc.) upheld Dr. Stewart in every detail. In spite of the hemolysis and the fact that the hemoglobin went to 32 per cent, the patient left the hospital with this blood count (August 26); erythrocytes 3,160,000, total leucocytes 9800, hemoglobin 65 per cent. Color index normal. Urine normal. Physical examination of patient negative. Blood pressure, sitting, 110.

August 30—Discharged, cured.

September 27—Condition excellent.

October 28—Continued improvement.

It is evident that a full and carefully made report of one severe case of puerperal septicopyemia, whose every detail, whether laboratory or clinical was noted, and whose every phase was recorded, must have a certain definite value. At least the writer feels that there was a time, not so very remote, when he would have gladly welcomed exactly such a history,—because it would have been a brilliant light where all was dark before. An abstract of such a case history is here given, with the understanding that the writer was in attendance, constantly, during the time the patient was in the Knickerbocker Hospital.

Mrs. C., a well developed and well nourished white female, thirty-two years of age, was admitted on June 27, 1921, giving a history of an incomplete abortion that occurred on June 20. Her mother had died of cancer of the uterus and the patient herself had had typhoid, the ordinary diseases of childhood, malaria, and dysmenorrhea. She had had two full term pregnancies and two miscarriages, having been married at the age of twenty. She entered the hospital at 10.30 P. M., with a profuse uterine hemorrhage, which was met with the usual measures, with small success. Consequently on the following day (June 28) she was curetted by one of the attending surgeons. She remained in the hospital until July 5, when she left against advice, though she was apparently in good condition On July 10 she returned with temperature 103°, pulse 120, respirations 24, and gave a history of a chill the previous day. The urine showed a faint trace of albumin and the blood count showed leucocytes 17,000. The hemoglobin was 60 per cent. Blood culture on agar plates showed small hemolytic colonies. Broth cultures showed numerous chains of *Streptococcus hemolyticus*. Uterine scrapings showed a practically pure culture of the streptococcus. The Wassermann and fixation tests for gonococci were negative. All sorts of treatments were used until the case was placed in Dr. Stewart's care on July 16, 1921, at which time the record was: temperature 104°, pulse 108, respirations 24, and the patient looked very sick. She had twenty-six colonies of bacteria to the plate. The next day she had fourteen colonies, and four days later she had none (July 21). July 28 showed nine colonies, after which there were none found. The pulse averaged 108 and the respirations 24 for the first ten days, while the temperatures ran from 98.5° to 105°. Then for seven days that temperature ranged from 98.5° to 102°, at the end of which time it ran up to 103°, pulse 110, respirations 20. After this the temperature varied from 99° to 101° for thirteen days, or until August 15, on which day it went to normal and there remained until the patient was discharged on August 30, 1921. The maximum pulse was 127 and the minimum 96 during the week from July 16 to July 23, and presented all qualities from bad to indifferent; but a statement of averages will suffice.

Metastases made their appearance and followed the course of the blood flow. The first one followed the channel of the left subclavian artery and appeared in the neighborhood of the left shoulder, while the second one, traveling by the same route, appeared at the left elbow, somewhat later in point of time. These two gave every promise of the usual and future severity. The third one appeared at the right shoulder, but was milder in onset and type than were its predecessors, and the fourth one was symptomatically but a pain and tenderness in the neighborhood of the fourth lumbar vertebra, practically corresponding to what might be expected from a sore spot, or from a damage to the bifurcation of the abdominal aorta. In disappearance the aforesaid metastases did not quite reverse the order of arrival, because the left elbow recovered last. The order of onset might be termed 1, 2, 3, 4; but that of cessation was 4, 3, 1, 2. In other words, there were four direct hematogenous metastases with a reasonable certainty of further and future lymphogenous transfer and transportation, had these not been forestalled by the arrest and nullification of the activities of the streptococcus, together with the detoxication and the elimination of its toxines from the blood stream, in which last their presence and their absence were both demonstrated by the laboratory. Incidentally a question arose as to how low the erythrocyte count will fall in a bacteriemia with a hemoglobin of about 30 per cent. The answer of the laboratory is that it will go to 1,000,000 or about one-quarter of the patient's normal.

The local treatment that proved best when directed against the aforesaid metastases was an application of an inch-thick cataplasmoid layer of bicarbonate of soda mud. This was covered with gauze, held in place by proper bandages, and the whole was kept wet by soaking an occasional tablespoonful of Wright's solution through the dressing. This seemed to work very well. It was not used once or twice; but was kept on the joint until pain and swelling disappeared. Which disappearance came to pass in such a reasonable time as to win the approval of physicians and patient.

To aid elimination, one ounce an hour of liquor potassii citratis, well diluted, was given by the mouth. The ordinary stimulants were employed when indicated. But the rectal administration was the all-important measure. At 8 A. M. and 8 P M. daily the rectum was carefully washed out with warm physiological salt so-

lution. This washing was followed by a two quart enema of a 5 per cent. sodium bicarbonate solution. What amount of this was retained was absorbed and acted as a catalyzer, what amount ran away into the pan simply washed away the mucus that would have prevented the action of the silver. Finally an absorbable retainable solution of 5 per cent. silver colloid was introduced, to the amount of four ounces. This was changed in forty-eight hours to a 6 per cent. strength, which proved entirely satisfactory, and therefore was employed twice daily for ten days, then once daily for a week. After this time it was used on Mondays and Fridays until August 15, when there was no further need for its employment.

The only two symptoms that Dr. Stewart seemed to await with anxiety were the disappearance of the bacteria from the broth cultures and the appearance of an appetite that would "surprise the staff." He surely obtained both. The amount of food that the patient ate was a standing joke to nurses and all concerned. Call it *incredible*, for lack of a better term. But its interest to the writer lay in the fact, that no matter where the temperature stood nor what the pulse was doing, if there were no bacteria in the blood then that appetite was extraordinary. Yet the digestive powers seemed to keep pace with it, and they proved fully equal to all demands. Needless to say the food was plain, nutritious, and carefully selected.

January 20, 1922.—Patient states that she never in her life felt so well, slept so well, weighed so much, or had such a stock of untiring energy.

In conclusion it may not be amiss to quote from Chemical Pathology, "Leucocytes contain substances which are strongly bactericidal, are independent of the action of the blood serum, and which have been called endolysins." Again, "Within the cell the enzymes exist in an inactive condition or form, the *zymogen*. The activation appears to take place only after they have been discharged from the cell." Very well, then the history here set forth may be termed the record of an attempt at bombarding hemolytic streptococci in the blood-vessels, by discharging endolysins at them, with a successful issue to the battle.

EXOPHTHALMIC GOITER AND DIGITALIS.

By ISRAEL BRAM, M.D.,

PHILADELPHIA, PA.

INSTRUCTOR IN CLINICAL MEDICINE, JEFFERSON MEDICAL COLLEGE.

THE reason for failure of the average internist's efforts to obtain recovery in exophthalmic goiter is not the stubbornness of the disease to the effects of remedial measures, far less the incurability of the affection. The prognosis in the average case of Graves' disease is far brighter than that in the average case of pulmonary tuberculosis, and recovery is far more conclusive. The difficulty lies not in the disease, but with the medical attendant. Graves' disease, so widespread in etiology, so generalized in symptomatology, so variegated in its clinical picture, requires likewise a régime of therapeutic measures so discriminating in nature that the patient cannot help but respond favorably. The etiology, the symptomatology, the entire clinical picture, and the physical and mental peculiarities in each patient are distinctly different from those observed in all other patients. It is these numerous differences that must be ferreted out, evaluated, and employed as a basis for individual therapeutic approach. The success or failure of the internist's *pretherapeutic* process of individualization determines the success or failure of even a most skillful therapeutic approach. Individualization is necessarily the keynote in the management of Graves' disease, and briefly stated, embraces the matter of a penetrating etiological investigation, precision in observation of subjective and objective symptomatology, a humane interest in psychology and applied psychotherapy, a study and correction of the patient's environments, an enthusiastic attitude toward the generally neglected subject of practical dietetics, and, finally, the scientific administration of drugs. With regard to drugs, it must be emphasized that it is as important to know what *not* to give as to know what to give. We might discuss at length drugs contraindicated in Graves' disease; we might go into detail on the occasional virtue but usual harm wrought by the administration of thyroid extract, the opiates, the iodides, and other substances. The drug least dwelt upon by most writers, and most often erroneously employed in this disease, is digitalis, and I beg leave briefly to present my views on this topic.

The constancy of heart hurry in the symptomatology and diagnosis of Graves' disease has led (often primarily) to the use of remedies destined to reduce the heart rate. From the use of "heart stimulants"* as the mainstay in the treatment of the disease, to their inclusion merely as a nonessential constituent of a broad régime of dietetic, hygienic, medicinal, psychotherapeutic, and other measures, many gradations of importance have been assigned to remedies administered for the purpose of stabilizing the circulatory system. Of all the remedies falling under this heading, digitalis, rightfully and otherwise, occupies first place.

Digitalis, employed in Graves' disease, may serve somewhat to regulate a delirious heart or a heart in a state of flutter or fibrillation, but due caution must be observed lest the apparent good be overbalanced by harm. Digitalis may help, more often hinder, and at times render impossible, recovery from this disease. Sufferers from Graves' disease, singularly tolerant to large doses of quinine and its salts, are singularly intolerant to digitalis and its products.

If we recall that the tachycardia of Graves' disease is constant, even during sleep, and that the heart rate is not influenced by digitalis even in massive doses, we are at once struck with the persistent stubbornness of the heart "drive" and the apparent antagonism of the driving agencies—the neuroendocrine *vis-a-tergo* — to this drug. The same might be remarked of digitalis in paroxysmal tachycardia. Administered during the active stage of Graves' disease, when the basal metabolism is high or rising, digitalis is not only useless, but is capable of increasing the subjective and objective heart symptoms. Moreover, the digestive difficulties are increased. In this relation another vicious circle is added to those already characterizing this affection, viz., the sensitiveness of the gastric mucosa is increased by contact with digitalis, resulting in flatulence, nausea, and vomiting, reducing the intake of food and the weight of the patient, *thus aggravating the entire syndrome and increasing rather than reducing the heart frequency.* This, in turn, increases the intolerance to digitalis.

*I believe the term "vascular stabilizer" to be more consistent with the physiological conception implied by "heart stimulant."

On the other hand, digitalis may be employed advantageously during the passive stage of Graves' disease. By the "passive stage" is meant that period during the course of the affection when spontaneously or as the result of treatment, the basal metabolism is less than + 15, the patient is gaining rather than losing weight, and there is subjective and objective improvement. Ordinarily, when, after several months of properly applied nonsurgical management of a given patient, there is a restoration of weight, marked improvement in or disappearance of the thyroid swelling and of exophthalmos, and recovery of the central and peripheral nervous symptoms—in a word, when the patient thinks, acts, and appears normal, the heart rate, too, is returned to normal. Occasionally, however, the heart rate is still 90 or above, its restoration seeming to lag for an indefinite time behind the general improvement or recovery elsewhere. This is by no means an indication of failure in treatment; it is seen in tardy convalescence from other illnesses, notably influenza, typhoid fever, and pneumonia. The myocardium is still in a state of disturbed function from the persistent action of former toxins; its nervous mechanism is still in a state of disequilibrium. Possibly the socalled "morbid habit of tissues" plays its part; if a whole individual can acquire a bad habit, surely a part may also acquire a bad habit necessitating correction—and the most efficient corrective here, at this time, is digitalis. To repeat, it is when the patient seems entirely recovered, when everything appears normal but the heart rate, that digitalis is indicated and is efficient as a restorer of vascular stability. It is then that the patient not only tolerates the drug, but responds promptly to its action.

The digitalis having accomplished its purpose within three or four weeks, its service seems no longer to be required, and it is withdrawn. In the majority of patients, the heart rate will now remain normal. Occasionally, the heart rate will soon again extend beyond normal, though not to the previous figure. Digitalis is again administered for a like period, after which it may be withdrawn permanently. In rare instances, it may be necessary to prescribe the drug during three or four such periods with intervals of a week or two, depending upon individual circumstances, especially the previous severity and duration of the disease and the damage it has wrought upon the myocardium and its regulating mechanism.

When, in the presence of the indications above mentioned, digitalis is deemed necessary, a reliable preparation should be selected. I have found a fresh, well standardized extract of the leaves serviceable, in that it can be combined in capsule with other ingredients then employed. The dose varies with the age and prevailing circumstances of the individual. I find that ¼ to ½ grain t.i.d. is quite sufficient in the average patient. Digitora (Upjohn) seems to possess advantages over the ordinary stock extract and may be administered in doses of one grain t.i.d. If, for some reason, a liquid preparation of digitalis is desired, digalen, minims five to ten t.i.d.; well diluted, will serve the purpose. With regard to dosage, it is well to observe that under no circumstances should we administer a quantity of the drug corresponding to an overdosage. It is far preferable to give too small a dose and await results, than a so-called physiological dose in which results seem prompt, but in which there is danger of deranging the recently recovered but still delicately balanced circulatory and gastrointestinal systems.

Conclusions.—1. In occasional instances, in the presence of auricular fibrillation or flutter, the careful intermittent administration of digitalis may serve to *regulate the action* but not to *lessen the frequency* of the heart rate during the active stage of Graves' disease.

2. In the great majority of patients, digitalis is useless in the tachycardia during the active stage of Graves' disease.

3. The drug may indeed aggravate the syndrome during the active stage of the disease.

4. Digitalis may be employed to advantage in patients who, though recovery is at hand, still present a degree of tachycardia.

5. The digitalis must be a reliable preparation and should be administered by one thoroughly familiar with this type of patient.

1431 Spruce Street.

MOONSHINE WHISKEY PSYCHOSIS.

By B. LEMCHEN, M.D.,

DUNNING, ILL.

PHYSICIAN OF THE CHICAGO STATE HOSPITAL.

We have, so far, no way to ascertain how moonshine whiskey acts on normal people. As a rule, all the people who are at present using moonshine have used alcohol before. However, the users of moonshine do not develop the psychosis common to chronic alcoholics, namely, delirium tremens, alcoholic hallucinosis, and alcoholic paranoid, but the most common psychosis developed in those who are indulging in moonshine are stuporous states in which the patient becomes more or less unconscious and from which he either dies or recovers, and when he does recover he does not remember anything that happened to him during the time he was unconscious. He either did not experience any form of hallucinosis, or when he did he does not remember any. He may perform almost any act while under the influence of moonshine, but after he recovers he remembers nothing that he has done. This resembles what we call pathological intoxication, or epilepsy or its equivalent. When they do develop a hallucinosis, it is mostly of the visual type instead of the auditory in the chronic alcoholics. Usually they see strange people with weapons who are trying to harm them, and as a rule they have no amnesia differing from that of delirium tremens in the chronic alcoholics, where they see mostly animals and have amnesia. This goes to prove, in part at least, that the form of psychosis a person develops depends more on the toxins circulating in his body than on inherited tendencies. Apparently different toxins attack different nerve cells. While the nonvolatile alcohol in bonded whiskey seems to intoxicate the nerve cell in the special centers, and we have in the majority of cases different forms of hallucinosis, the volatile alcohols in moonshine seem to attack the nerve cells in the associated centers, and in the majority of the moonshine cases we have all

degrees of unconsciousness, with impairment of judgment. For illustration, I will cite a few cases that have been admitted to the Chicago State Hospital in the past few years:

CASE I.—Frank H., admitted to the Chicago State Hospital September 15, 1921. History given by a son-in-law as follows: Patient was a heavy drinker until the country went dry, but had never shown any mental symptoms. From that time he did not drink until a couple of weeks before he was admitted, when he met a friend who gave him moonshine. He got drunk that day, had a quarrel with his wife and left the house, returning in the evening when no one was at home. He went to the basement, set fire to his house and then left. He went out to the Forest Preserve and cut his left wrist at 9 o'clock that evening. Neighbors found him there and took him to the Chicago Heights Hospital. When he went home his family had him taken to the Psychopathic Hospital. The Psychopathic Hospital record states as follows: Physical: senile changes; recent incision on left wrist. Mental: good response to mental tests; patient is quiet, cooperative and in good contact; has swings of mood. Says he noticed his wife was in love with another many. She goes to the window to see a neighbor pass. He became drunk and cut his wrist with a razor. When he was admitted to the Chicago State Hospital, he was clear and oriented in all spheres. He stated he was 65 years old, born in Germany in 1856. Has been in the United States since 1877. He is a citizen. Is an iron moulder by trade. Says that on August 15, a neighbor gave him some moonshine, and in an hour later he did not know what happened to him until he found himself at midnight in the Chicago Heights Hospital. Then he found out that he had cut his left wrist, but he does not remember having done it. He was in the Chicago Heights Hospital two weeks and four days. When he left there he stayed with a married daughter. On Labor Day he went to his home and when his people saw him they became frightened and locked the doors and would not let him in. They sent for the police and had him taken to the Psychopathic Hospital. His general knowledge was good and he did the ordinary tests correctly. Physically, with the exception of an infected wound on the left wrist, and a few senile changes, the examination was practically negative. The patient remained in the hospital until November 11, 1921, when he was paroled to his son in good physical and mental condition. In fact, he had shown no mental symptoms during his stay in the Chicago State Hospital.

CASE II.—Joseph P., admitted to the Chicago State Hospital October 22, 1921. History given by a friend as follows: Patient is 39 years old. Born in Poland; in the United States 15 years. For some time patient had been talking queerly; would tell imaginary people to open the door. At night he was afraid, and could not sleep. Thought he saw a lot of people after him. The psychopathic record states: Physical, negative. Mental: Orientation, memory, and judgment, good; retention, general information, and calculation poor. Patient is quiet and cooperative, but in poor contact. Emotional attitude fairly adequate. Answers questions to the point. Saw large black dogs and black people with sticks jumping on him. Has been out of work for 9 months. The patient is a chronic alcoholic. When admitted to the Chicago State Hospital, he was clear and oriented. He told the examiner that he went to the County Hospital to be treated for pain under the eyes, and from there he was sent to the Psychopathic Hospital. He stated that while he was at home he saw black people and black dogs, but he was not especially frightened by them. He denied ever hearing voices. Admitted having drunk home brew whiskey. His general knowledge was in keeping with his station, and his physical and laboratory examinations were negative. Patient got along well while at the Chicago State Hospital, took an interest in the hospital activities, and behaved in a normal manner.
